SCHÜTZ *TO* SPEKE

SCHÜTZ, HEINRICH (1585–1672), the greatest German composer before J. S. Bach, was born on Oct. 8, 1585, at Köstritz. In 1599 he became a chorister at Kassel where the landgrave of Hesse-Kassel provided him with a wide general education. In 1608 Schütz entered the University of Marburg where he began to study law, but in 1609 he went to Venice where for three years he studied music at the landgrave's expense; his chief teacher there was Giovanni Gabrieli. In Venice Schütz wrote his first known works, a set of Italian madrigals for five voices (1611). In 1613 he returned to Germany and went to Leipzig to resume his legal studies; shortly afterward, however, the landgrave offered him the post of second organist at the court in Kassel. In 1614 he went to Dresden to supervise the music for the christening of the son of the Elector of Saxony, and eventually the landgrave was persuaded to allow him to take a permanent post in the electoral chapel. In 1619 he married Magdalene Wildeck, who bore him two daughters. In 1628 Schütz again visited Venice where Claudio Monteverdi was now the chief musical figure; it is possible that Schütz studied with him. Three years after his return to Dresden, Schütz left the elector's court, which was being seriously affected by plague and by the turmoils of the Thirty Years' War, and from 1633 to 1635 he was *Kapellmeister* to the royal court of Copenhagen. From 1635, apart from further visits to the Danish court, he remained, in spite of his frequent pleas for dismissal, in the elector's service at Dresden until his death there on Nov. 6, 1672.

After the early set of madrigals, almost all Schütz's known works are vocal settings of sacred texts, with or without instruments. Of his known secular works, *Daphne* (1627), the first German opera, and compositions for the marriage of Johann Georg II of Saxony in 1638, were lost. Schütz's special achievement was to introduce into German music the new style of the Italian monodists (as typified in Monteverdi's work) without creating an unsatisfactory hybrid: his music remains extremely individual and German in feeling. After the Latin of *Symphoniae sacrae I* (1629) he used the vernacular. The first German requiem was his *Musikalische Exequien* (1636), for soloists and choir, in which the writing for solo voice or duet is often florid in the Italian manner, while the choral sections are firmly based on German chorale tradition. The final section is for double choir, a form which recalls Schütz's studies with the earlier Venetian composers. Other principal works from the middle of his life are two sets of *Kleine geistliche Konzerte* (1636, 1639) for solo voice and continuo, *Geistliche Chormusik* (1648), and *Symphoniae sacrae II* and *III* (1647, 1650) for various combinations of voices and instruments. In all these Schütz's strong dramatic sense is noticeable. The Christmas oratorio of 1664 for soloists, choir, and instruments foreshadows his austere last works. These are *a cappella* Passions, settings of the text of the Gospels according to Matthew, Luke, and John; in these works even the sparing vocal figuration of the Christmas oratorio is absent. The plain scriptural text is delivered by the appropriate soloist in a kind of recitative, generally syllabic, while the words of the Jews, high priests, etc., are set as brief polyphonic choruses.

A complete edition of Schütz's works was begun in Germany in 1955. (C. P. Co.)

SCHWÄBISCH GMÜND, a town in the *Land* (state) of Baden-Württemberg, Federal Republic of Germany, lies in the valley of the Rems, 33½ mi. (54 km.) E of Stuttgart. Pop. (1961) 41,050. It is a centre of the jewelry industry and after World War II craftsmen from Gablonz (Jablonec), Czech., introduced the manufacture of glassware. Besides the Romanesque Johanneskirche and the Gothic Heiligkreuzmünster the town has half-timbered, Baroque, and Rococo houses, and remains of the old surrounding walls. It was chartered in 1162.

SCHWANN, THEODOR (1810–1882), German physiologist known as the co-originator, with M. J. Schleiden, of the cell theory, and the first to use this term, was born at Neuss in Rhenish Prussia on Dec. 7, 1810. After studying at Cologne, Bonn and Würzburg, he graduated in medicine at Berlin in 1834. There he assisted Johannes Peter Müller (*q.v.*) with his experimental work in physiology. Schwann in 1838 was called to the chair of anatomy at the University of Louvain, and in 1847 went as professor to Liège, where he continued until his death, at Cologne, on Jan. 11, 1882. While working with Müller, Schwann's attention was directed to the physicochemical basis of life. Between 1825 and 1837 several workers demonstrated that yeasts of beer and wine are cells that multiply by budding.

In 1839 Schwann was the first to observe internal spores of yeasts, and demonstrated the necessity to digestion of the presence

of a ferment which he called pepsin. In 1837 he began to investigate the laws of muscular contraction, discovering the striated muscle in the upper part of the esophagus, and, later, the myelin sheath, covering the peripheral axons, which now bears his name (*see* REGENERATION: *Nerve Regeneration*). Schwann's *Microscopic Investigations on the Accordance in the Structure and Growth of Plants and Animals* (1839; Eng. trans., 1847) set forth his hypothesis that both animal and vegetable tissues are to be traced back to cells and that the cells of each are identical in character. His cell theory was taken up by Rudolf Virchow (*q.v.*), who disproved Schwann's hypothesis of the discontinuity of cell formation.

SCHWARZBURG, a Thuringian dynasty which gave its name to two sovereign states in Germany before 1918. The ancestors of the dynasty were counts of Käfernburg, a castle near Arnstadt on the Gera River south of Erfurt, in the 11th century. By 1109 they were also counts of Schwarzburg, another castle, on the Schwarza River west of Saalfeld. The two sons of Count Günther III (d. 1196) divided their lands between Käfernburg and Schwarzburg lines. The Käfernburg line died out in 1385, and its lands (including Saalfeld) passed to the rival dynasty of Wettin (*q.v.;* and *see* also SAXONY; THURINGIA). Meanwhile the Schwarzburg line was from 1275 split between Schwarzburg-Schwarzburg and Schwarzburg-Blankenburg branches (the modern Bad Blankenburg stands northeast of the old Schwarzburg). Schwarzburg-Schwarzburg between 1305 and 1334 got possession of Rudolstadt, on the Saale River just below the Schwarza confluence; and about 1330 it acquired Leutenberg, on the Sormitz tributary of the Saale above Saalfeld, so that it was subsequently known as the Schwarzburg-Leutenberg line. When it died out in 1564, its lands reverted to Schwarzburg-Blankenburg. The latter line had provided a German king in 1349 (*see* GÜNTHER); but of more historical consequence was its acquisition of Frankenhausen in the 1340s and of Sondershausen in 1356, since both these lands, beyond the Unstrut River, lay considerably to the north of the main Schwarzburg block. In Thuringia, the Schwarzburgs and the separate dynasty of Reuss (*q.v.*) were ultimately the only ones to conserve independence from the more powerful House of Wettin.

Though the Blankenburg lands had been subdivided, Günther the Rich (d. 1552) reunited them all. He also adopted Lutheranism. After the Leutenberg inheritance, his sons effected another partition, from which the lines of Schwarzburg-Sondershausen and Schwarzburg-Rudolstadt emerged (1584). Both Sondershausen and Rudolstadt, however, had exclaves in one another's vicinity.

Despite Wettin objections, the counts of Schwarzburg-Sondershausen were recognized as princes of the Holy Roman Empire in 1697, and those of Schwarzburg-Rudolstadt in 1710. Both principalities, as sovereign states, entered the Confederation of the Rhine in 1807 and the German Confederation in 1815 (*see* GERMANY: *History*). Schwarzburg-Rudolstadt received a constitution in 1816, and another in 1854, modified in 1870; Schwarzburg-Sondershausen received one in 1841 and another in 1849, superseded in 1857 (with many subsequent modifications). Both states declared themselves for Prussia in the Seven Weeks' War and entered the North German Federation (1866) and the German Empire (1871). On the death, childless, of Charles Günther of Sondershausen in 1909, both states came under the rule of Günther Victor of Rudolstadt, in personal union. On the German Revolution of 1918 the prince abdicated, and both states became republics before merging themselves, in 1920, in the new state Thuringia (*q.v.*).

SCHWARZENBERG, FELIX, PRINCE ZU (1800–1852), Austrian statesman who restored the Habsburg monarchy to prestige as a great power after the revolutions of 1848–49, was born at Krumau in Bohemia on Oct. 2, 1800, the second son of Joseph, prince zu Schwarzenberg. He entered the army in 1818, but was transferred to the diplomatic service (without resigning from the army) in 1824 and worked in the embassies in Lisbon, St. Petersburg, Paris, and London (where his amour with Jane, Lady Ellenborough, wife of the lord privy seal, led to her being divorced). A protégé of Metternich, he was appointed Austrian minister to Sardinia-Piedmont in 1838 and to the Kingdom of the Two Sicilies in 1844.

During the Neapolitan revolution of 1848 Schwarzenberg returned to Vienna. Having meanwhile been promoted to the rank of general, he then joined Joseph Radetzky's army in northern Italy (*see* ITALIAN INDEPENDENCE, WARS OF). Wounded at Goito, he was sent back to Vienna to dissuade the government from surrendering Lombardy and to obtain reinforcements for Radetzky. Successful in this mission, he was appointed military governor of Milan, but soon returned to Vienna to have his wound treated.

When revolution broke out in Vienna on Oct. 6, 1848, Schwarzenberg tried to induce the military commander to make a stand and remained there till Oct. 13—four days after being summoned to join the imperial court, then on its way to Olmütz. On the advice of his brother-in-law, Alfred, prince von Windischgrätz (the field marshal on whom the court depended), Schwarzenberg was bidden to form a government on Oct. 19. On Nov. 21 he was declared prime minister and foreign minister.

Schwarzenberg procured the abdication of the imbecile emperor Ferdinand (Dec. 2, 1848) and the elevation to the throne of the 18-year-old Francis Joseph (*q.v.*). From the first he showed regard for the young emperor's self-respect: he always presented his advice in such a way that Francis Joseph could believe himself to have made the decisions.

Schwarzenberg at first seemed ready to cooperate with the Kremsier Parliament (*see* AUSTRIA, EMPIRE OF). On March 4, 1849, however, he imposed on the monarchy a totally centralistic constitution; and on March 7 he dissolved the Kremsier Parliament. His policy of centralization displeased Windischgrätz, who thought that order could be restored only if the various lands of the empire preserved their historic autonomy. Dissension grew worse when Windischgrätz demanded that Austria accept Russia's offer of military help to suppress the Hungarian rebellion. Schwarzenberg, seeing how humiliating this would be for Austria, engineered the recall of Windischgrätz from the command in Hungary (April 13); but a few days later, with Hungary almost completely overrun by the rebels, Schwarzenberg had to accept Russia's offer.

The defeat of the revolution convinced Schwarzenberg that the various nations of the Habsburg monarchy had forfeited their historic rights. In his centralizing policy he was upheld by his two successive ministers of the interior—namely Franz, Graf von Stadion, and Alexander, later Freiherr von Bach—and, not least, by the emperor himself. Schwarzenberg wanted to use the army and the civil service as the basis for the reconstruction of the state, in which the Germans were to have the leading role. He consequently sought to enhance Austria's position within the German Confederation, into which he wanted to bring the whole Habsburg monarchy, so as to realize the economic "empire of 70,000,000" envisaged by his minister of commerce, Karl Ludwig von Bruck.

When the National Assembly at Frankfurt abortively offered the German imperial crown to Frederick William IV of Prussia (*see* GERMANY: *History: The German Confederation, 1815–66*), Schwarzenberg recalled the Austrian delegates from the Assembly. As he could not conciliate Prussia, he began trying to revive the Confederation in its old form. In May 1850 a federal diet met again in Frankfurt, comprising representatives of Austria and ten German states; and Schwarzenberg, who could rely on a well-organized army, then prepared for war against Prussia. Diplomatic intervention by Russia checked his plans at the last moment, but even so, at Olmütz in November 1850, he forced the Prussians to renounce their scheme for a united Germany without Austria. At the Dresden conference of the German states, however, his plan for a reform of the federal constitution and for the admission of all the Habsburg lands into the Confederation was rejected. He did not even manage to introduce Austria into the German customs union.

By the so-called *Silvesterpatent* (New Year's Eve decree) of Dec. 31, 1851, Schwarzenberg abolished the constitution granted in 1849. This abolition not only damaged the prestige of the young emperor, whom Schwarzenberg thus induced to break his word to his subjects, but also inaugurated an era of neo-absolutism.

Schwarzenberg died in Vienna on April 5, 1852. His death was an irreparable loss for the emperor Francis Joseph. Handsome and pleasure-loving, he had been a coldly realistic aristocrat. He had led Austria back to its old eminence as a great power after the most serious crisis of its history. His political concepts were clear, and he was prompt to perceive the right solution for the problems of international affairs. Yet in domestic affairs the return to German-based centralism became meaningless when Austria could not win hegemony in Germany; and the repeal of the constitution left only a shaky foundation for the great power which Schwarzenberg had resurrected.

SCHWARZENBERG, KARL PHILIPP, Prince zu (1771–1820), Austrian field marshal and diplomat, one of the foremost personalities of the Napoleonic Wars, was born in Vienna on April 15, 1771, the son of Prince Johann Nepomuk zu Schwarzenberg. Joining the army in 1787, he served against the Turks in 1788–89. Promoted major as early as 1790, he proved his talents as a cavalry leader in the War of the First Coalition against France (*see* French Revolutionary Wars). He was promoted general in 1796 and lieutenant field marshal in 1800. In the War of the Second Coalition (*see* Napoleonic Wars) he covered the withdrawal of the right wing of the archduke John's army after the defeat at Hohenlinden (1800). In the War of the Third Coalition he won a victory at Jungingen and managed to reach Bohemia with his division after the defeat at Ulm (1805). Vice-president of the Supreme War Council from 1805 to 1808, he had a share in the army reform which made possible Austria's initial successes in the war of 1809. Meanwhile, he had undertaken diplomatic missions to Russia (1801), to Bavaria (1805), and to Russia again (1808–09); on this last mission, he persuaded the Russian emperor Alexander I to delay his support of the French in the war of 1809. In the Battle of Wagram (1809) Schwarzenberg distinguished himself in command of a cavalry corps.

After the Peace of Vienna (Schönbrunn), Schwarzenberg went as ambassador to France. He thus helped to negotiate the marriage between Napoleon and Marie Louise (1810) and the agreement for the war of 1812 against Russia. Napoleon appreciated Schwarzenberg's qualities and wanted him to command the Austrian forces against Russia, since the archduke Charles refused to do so. Schwarzenberg accepted this post, but conducted himself in accordance with Metternich's policy of holding back; and his retreat into Austrian territory in the winter of 1812–13 greatly facilitated the junction of the Russians with the Prussians. Thereafter he was a spokesman for bringing Austria into the war against Napoleon. When this policy prevailed (August 1813), he was promoted field marshal and was made supreme commander of the principal force of the Allies. Following the plans of Joseph Radetzky (*q.v.*), he united the Allied forces for the Battle of Leipzig (*q.v.*) in October. He likewise directed the operations of the main army in France in 1814.

When the Congress of Vienna (*q.v.*) was reorganizing Europe, Schwarzenberg stressed the military objections both to a revival of the Habsburgs' imperial authority in Germany and to a restoration of the former Habsburg possessions on the Upper Rhine, since such measures would have overtaxed Austria's strength. He also opposed Prussia's demand for the whole of Saxony, since this would have meant the encirclement of Bohemia. Prematurely aged, he suffered a paralytic stroke in 1817 and died at Leipzig on Oct. 15, 1820. His letters to his wife, Maria Anna Theresia, Gräfin von Hohenfeld, whom he had married in 1799, are edited by J. F. Novak (1913).

SCHWARZSCHILD, KARL (1873–1916), German astronomer, whose researches were of great range and versatility, was born on Oct. 9, 1873, at Frankfurt am Main, Ger. His exceptional ability in science was evident in a paper on the theory of celestial orbits he wrote at the age of 16. As a student, Schwarzschild came under the inspiration of the astronomer Hugo von Seeliger at Munich. In 1901 he became professor and director of the observatory at the University of Göttingen, leaving in 1909 to become director of the Astrophysical observatory at Potsdam. He served actively in World War I, during which he contracted an illness of which he died on May 11, 1916, at Potsdam.

Schwarzschild's contributions to physical science are significant in several fields. In observational astronomy, he was the first to introduce and apply precise methods in photographic photometry; the first to employ a coarse grafting in front of the telescope objective for photometric and astrometric work; and he developed certain basic methods of analysis of solar spectra taken during eclipses. In theoretical astronomy Schwarzschild introduced the concept of radiative equilibrium in astrophysics and was the first clearly to recognize the role of radiative processes in the transport of heat in the atmospheres of the stars. He also initiated some basic mathematical methods for the treatment of these problems.

Schwarzschild laid the foundations of modern statistical methods in astronomy, and also made the most important contributions, after Carl Friedrich Gauss, to geometrical optics and the theory underlying the design of optical instruments.

Although generally considered an astronomer, Schwarzschild also made fundamental contributions to theoretical physics and to relativity. In the former, he was one of the great pioneers in developing Niels Bohr's theory of atomic spectra. In a great paper, the proofs of which he read on his deathbed, Schwarzschild developed (independently of Arnold Sommerfeld) the so-called general "rules of quantization" and gave the complete theory of the Stark effect and initiated the quantum theory of molecular spectra. Similarly, in developing the general theory of relativity, Schwarzschild gave the first exact solution of Einstein's general gravitational equations leading to the discovery of what is now called Schwarzschild's line element describing the geometry of space in the neighbourhood of a mass point. (Su. C.)

SCHWEINFURTH, GEORG AUGUST (1836–1925), German botanist and traveler who made his name as the explorer of the Bahr el Ghazal region of the west Nile Basin, was born in Riga on Dec. 29, 1836, the son of a German wine merchant who had settled in Riga. He studied botany at Heidelberg and Berlin and early became interested in the plants of Africa. In 1863 he traveled down the Red Sea to Suakin and overland to Khartoum, botanizing as he went. On his return to Berlin in 1866 he interested the Royal Academy of Science in the botanical exploration of the hitherto little-known region watered by the Bahr el Ghazal, for which he received a grant from the Humboldt Institute. Arriving at Suakin in Sept. 1868 and at Khartoum in Jan. 1869, he ascended the White Nile and traveled westward by way of Lake No with a party of ivory traders.

Primarily a botanist, Schweinfurth had also a good knowledge of zoology and ethnology; he spent nearly three years in the region, visiting the Niam-Niam, the Bongo, and the Mangbetu peoples; and his is the first authoritative account of the Congo pygmies. Crossing the Nile-Congo watershed he reached, in March 1870, the westward-flowing Uele, later discovered to be an affluent of the Congo. He received the Royal Geographical Society's Founder's Medal for 1874, his discovery of the Uele having helped toward a final estimate of the extent of the Nile system.

From 1875 to 1888 Schweinfurth lived in Cairo, traveling each winter, notably to the Lebanon in 1880, Socotra in 1881, and the Yemen in 1888, interesting himself in botany, geology, paleontology, and archaeology. In 1876 he attended the African conference summoned to Brussels by King Leopold, and in 1888 moved to Berlin where his herbarium was housed. Until 1914 he went to Africa frequently. He died in Berlin on Sept. 19, 1925. He was a keen observer and an accurate and humorous recorder; *The Heart of Africa* (1873) is excellent reading and a reminder of the part played by German explorers in African discovery.

See S. Passarge, *Mitteilungen der Geographischen Gesellschaft in Hamburg*, vol. 37 (1926); and an unsigned obituary in *Geogr. J.* vol. 67 (1926). (D. Mn.)

SCHWEITZER, ALBERT (1875–1965), Alsatian philosopher, theologian, musician, mission doctor, and winner of the Nobel Peace Prize in 1952, was born on Jan. 14, 1875, at Kaysersberg, Upper Alsace, the eldest son of a Lutheran pastor. The family soon moved to Günsbach, in the Münster Valley, which remained Schweitzer's European home. At the *Gymnasium* at Mühlhausen, where he went when he was 9, he showed interest in history and natural science. At 18 he entered Strasbourg University to study theology and philosophy. His mind soon began to turn to the problems of the Synoptic Gospels, and during his military service (1894) he pursued the researches into the life of Jesus which, despite many other labours, he continued throughout his life. After studying in Paris, he took his doctorate in philosophy at Strasbourg with a treatise on *Die Religionsphilosophie Kants* (1899). He then studied at Berlin, returning to Strasbourg as lecturer in philosophy and preacher at St. Nicholas' Church, and taking his doctorate in theology in 1900. In 1903 he became principal of a theological college attached to the university. He had already published, in 1901, *Das Abendmahlsproblem auf Grund der wissenschaftlichen Forschung des 19. Jahrhunderts und der historischen Berichte* and *Das Messianitäts- und Leidensgeheimnis Jesu* (Eng. trans., *The Mystery of the Kingdom of God*, 1914), preparing the way for *Von Reimarus zu Wrede: eine Geschichte der Leben-Jesu-Forschung* (1906; *The Quest of the Historical Jesus: a Critical Study of Its Progress from Reimarus to Wrede*, 1910), which established him as a world figure in theological studies. In these, he made a radical and exhaustive demonstration of the eschatological view of the life of Jesus—the view that Jesus' ministry was dominated by his knowledge of his messiahship and his expectation of the imminent end of the world. In two books on St. Paul, notably *Geschichte der Paulinischen Forschung* (1911; *Paul and His Interpreters*, 1912), and in later and briefer writings, he continued to expound the view that the New Testament is pervaded by eschatological expectation.

SCHWEITZER

Meanwhile, Schweitzer was also studying music. He had begun his career as organist at Strasbourg in 1893, when E. Münch, the initiator and conductor of Bach concerts there, asked him to play the organ accompaniment for performances of Bach's cantatas and Passions. In Paris, he studied the piano with a former pupil of Liszt. Becoming interested (1896) in organ-building and restoration, he published in 1906 a booklet on the art of organ-building and -playing in France and Germany (Eng. trans. 1927). In 1902 C. M. Widor, his organ teacher in Paris, recognizing that, as well as being a gifted organist, Schweitzer was a Bach interpreter of rare and original perception, asked him to write a study of Bach's life and art. Although already working on *The Quest of the Historical Jesus*, Schweitzer agreed, and the intended essay grew into a substantial book, *Jean Sébastien Bach: le musicien-poète* (1905), written in French while he was lecturing and preaching in German at Strasbourg. Its publication brought him acclaim in France and Germany. Called upon for a German translation, Schweitzer rewrote the book in German at twice the length, and it was from this edition (1908) that the English translation (by Ernest Newman, with additions and corrections by Schweitzer) was made (two volumes, 1911). Following his usual practice, he gave the reader a thorough historical and analytical background of the subject, of the origins of the chorale, of the cantata, and of the Passion music; he reviewed the forms of music and art within the history of thought and presented Bach as a deeply religious mystic whose music was impersonal and unselfconscious, as cosmic as the forces of nature. In a style matching his theme, he described the composer as a musician-poet and the supreme pictorial artist in sound; and he gave detailed, copiously illustrated (and sometimes controversial) instructions for playing Bach's works. His *J. S. Bach* remains a classic study for the depth and breadth of its interpretation and for its rich spiritual content.

In 1905, a scholar and an organist of wide repute with an unbounded academic future before him, Schweitzer announced to his friends his intention to realize a decision made in 1896. He began to study medicine, to qualify himself as a mission doctor to the people of equatorial Africa, and in 1906 he resigned his university appointments. Later, in *Zwischen Wasser und Urwald* (1921; *On the Edge of the Primeval Forest*, 1922), he explained that he had found his simple motive in the parable of Dives and Lazarus (Luke 16:19–31), identifying Dives with the white man, endowed with all the benefits of culture and science, and Lazarus with the Negro, exploited and oppressed and lacking even medical treatment for his disease and pain. With characteristic thoroughness he took the six years' course in medicine and surgery, continuing meanwhile some of his major literary and musical work. In 1912 he married Hélène Bresslau, daughter of a well-known Strasbourg historian and herself an accomplished scholar, who trained as a nurse to share her husband's renunciation and adventure in discipleship until her death in 1957. In 1913 they went to the Gabon province of French Equatorial Africa (after 1960, the Republic of Gabon). The site for Schweitzer's hospital at Lambaréné, on the forested banks of the Ogowe (Ogooué) River, was provided by the Paris Missionary Society, which had declined his services because of his unorthodox theological views; but in all else his was an independent enterprise. He equipped and maintained his hospital from the proceeds of organ recitals and lectures on his visits to Europe and from royalties on his books (and later also from gifts and grants from individuals and foundations in many countries).

Building his hospital with his own hands and African help, operating far into the night under the most primitive conditions, and entering his long fight with leprosy, with sleeping sickness, and with a host of tropical diseases, Schweitzer began to turn his active intellect to the problem of world civilization. Opportunity for the development of his thought was given in 1914 by the brief internment at Lambaréné of himself and his wife as German subjects, and he continued to work more intensively on his thesis when in 1917 they were taken back to Europe and eventually (1918) to a prison camp in Provence. The outcome was the publication in 1923 of the first two volumes of his *Kulturphilosophie*. The first, *Verfall und Wiederaufbau der Kultur* (*The Decay and the Restoration of Civilization*, 1923), is a brief introduction, while the second, *Kultur und Ethik* (*Civilization and Ethics*, 1923), is a brilliant review of the history of ethical thought leading up to his own original and positive contribution of "reverence for life" as the true and effective basis for a civilized world.

Early in 1924 Schweitzer returned to Africa to rebuild his derelict hospital and to renew its work. Famine, pestilence, floods, and lack of adequate help made this fresh start even more formidable than the first beginning, and he decided to move to a better site about 2 mi. (3 km.) farther up the Ogowe. There his practical powers were devoted to the creation of a larger and more efficient hospital. Over the years the hospital village grew, and with the discovery of new drugs for the treatment of leprosy a large leper colony came into being near by. In April 1963, when he received an address of felicitation on the jubilee of Lambaréné from his supporters in 28 countries, there were in the hospital about 350 patients with their relatives, and in the leper colony 150 patients, all served by a staff of 30 white and 30 nonwhite doctors, nurses, and helpers.

Besides this principal preoccupation, Schweitzer published *Die Mystik des Apostels Paulus* (1930; *The Mysticism of Paul the Apostle*, 1931), more mature than his previous pieces of original New Testament scholarship; and *Die Weltanschauung der indischen Denker: Mystik und Ethik* (1935; *Indian Thought and Its Development*, 1936), a book that grew from one chapter of the draft of the continuation of his *Kulturphilosophie*. He returned for brief visits to his home at Günsbach (where he had used the proceeds of the Goethe Prize he received in 1928 to build a house for himself and his colleagues, and where he received many visi-

tors), and to give lectures and organ recitals in Germany, Great Britain, the Netherlands, Scandinavia, and France; and he accepted an invitation to take a leading part in the Goethe bicentenary celebrations at Aspen, Colo., in 1949. He also made recordings and resumed his editing of Bach's music, begun with Widor in 1911 (*Bachs Orgelwerke*, 1912–14). Intermittently he returned to the third volume of the *Kulturphilosophie*—though not with the intention that this should be published during his lifetime—and to a restatement of his theological thought. His address on receiving in 1953 the 1952 Nobel Peace Prize, *Das Problem des Friedens in der heutigen Welt* (1954; *The Problem of Peace in the World of Today*, 1954), had a worldwide circulation. He was received by Queen Elizabeth II in 1955 when he was appointed an honorary member of the British Order of Merit. In 1958 he broadcast from Oslo three appeals to the world, published as *Friede oder Atomkrieg* (*Peace or Atomic War?*, 1958). Schweitzer died at Lambaréné on Sept. 4, 1965, and was buried there.

Schweitzer's astonishing and lasting capacity for arduous physical and mental labour was supported by an exceptionally strong physique. Tall and broad, of relentless energy and acute concentration, his face at once forceful and compassionate, he had immediate and magnetic charm for all who met him. Shrewdness was evident in his business arrangements and in the administration of his hospital settlement, together with an almost patriarchal feeling in his retention of control over every detail of its work and management. The practical thoroughness underlying his powers of creation and interpretation was reflected also in his passion for the building and repair of organs and in his exhaustive mastery of the work of his predecessors in theology and philosophy.

Anderson, *The Schweitzer Album* (1965). (J. D. N.)

SCHWENCKFELD, KASPAR, von Ossig (1489–1561), German reformer and preacher, lay leader of the Protestant Reformation in Silesia, founder of a widespread movement known as the Reformation by the Middle Way, and spiritual ancestor of the Schwenkfelder Church, a small Protestant denomination extant in the United States. A prolific author, he laboured throughout his life for the principles of religious freedom, a labour which forced him into exile and hiding for the greater part of his career.

Schwenckfeld was born of the nobility and grew up on the family estate in Lower Silesia. He studied at the universities of Cologne and Frankfurt and served as counselor to various courts from 1511 until 1523. His spiritual awakening came in 1518. In 1525 he visited Martin Luther in Wittenberg to submit his views on the Eucharist. This conference closed on a note of complete disagreement, and Schwenckfeld returned to Silesia to further develop his own theology and reformatory plan. The Middle Way, as his approach was thereafter designated, endeavoured to strike a spiritual course between the Catholics and Lutherans, both of which, he claimed, were swerving away from Christ and dwelling on external symbols. He subsequently published strong anti-Catholic and anti-Lutheran views which resulted in his final dismissal by the duke of Liegnitz. In 1529 he voluntarily left Silesia, taking up residence at Strasbourg where he became acquainted with Sebastian Franck, Melchior Hoffman, Michael Servetus and Paracelsus. There, too, he encountered Huldreich Zwingli for the first time, although Zwingli had earlier published Schwenckfeld's book on the sacraments in Switzerland. They were unable to reconcile their differences, and Schwenckfeld was not invited to participate in the Marburg colloquy of 1529, where his views were subsequently dismissed. In 1533 Schwenckfeld defended his doctrines and the principles of religious liberty against Martin Bucer in the synod of Strasbourg. However, the leaders of the orthodox groups maintained their control over the synod and Schwenckfeld left Strasbourg, residing variously in Augsburg, Tübingen and Ulm. The publication (1539) of a book in proof of his most characteristic doctrine—the deification of the humanity of Christ—led to active persecution by the Lutherans and his expulsion from Ulm. The next year (1540) he published a refutation of the attacks upon his doctrine with a more elaborate exposition of it, under the title *Grosse Confession*. The book emphasized the differences between the Lutherans and Zwinglians on the doctrine of the Eucharist at a moment when efforts were being made to reconcile them. An anathema was accordingly issued from Schmalkald against Schwenckfeld (together with Sebastian Franck); his books were placed on the Protestant "index"; and he himself was made a religious outlaw. He went into hiding.

His followers then broke completely from orthodox church circles and formed small societies and brotherhoods. Schwenckfeld lived the life of a fugitive from 1540 until his death, frequently changing his abode, writing under a variety of pseudonyms and answering his critics with a constant flow of pamphlets and books. He died at Ulm on Dec. 10, 1561.

Schwenkfelder brotherhoods and conventicles remained active in southern Germany after his death, particularly in Strasbourg, Speyer and Ulm, but their vitality was virtually destroyed during the Thirty Years' War. The last important nucleus of adherents lived in the principality of Liegnitz, Lower Silesia. In 1719 a Jesuit mission was sent from Vienna to Silesia to convert them by force. In the wake of this effort, and its subsequent persecutions, more than 500 Schwenkfelders fled into Saxony and 200 of these ultimately found homes in the new world. When Frederick II (the Great) of Prussia captured Silesia in 1740, he extended his protection to those who remained in the province and issued an edict to the exiles in Pennsylvania, offering to return to them their expropriated homes if they would journey back to Silesia.

After 50 years of pioneer life in southeastern Pennsylvania, the exiles took their first steps toward formal organization, forming in 1782 the Society of Schwenkfelders. This society was the forerunner of the present-day Schwenkfelder Church, incorporated in 1909, consisting of five congregations, all near Philadelphia, with a combined membership of approximately 2,600 members. Each church is incorporated and self-sustaining, all joining in a general conference that meets twice yearly. Worship is nonliturgical and theology Christocentric.

SCHWERIN, a town in the northwest of the German Democratic Republic and the capital of the *Bezirk* (district) of Schwerin, lies on the southwest shore of the Schweriner See (lake), 111 mi. (179 km.) NW of Berlin by road. Pop. (1964) 91,210. Schwerin, which until 1952 was the capital of the *Land* (state) of Mecklenburg, was a Wendish settlement in 1018; the German town and its charter date from 1160. The urban district is dotted with lakes, and a 19th-century castle on the site of an earlier one stands on an island between the Schweriner See and Burg See. The cathedral, mainly Gothic (13th–15th century), was completed in 1892 with a tower 384 ft. (117 m.) high. The town's industries include the manufacture of machinery (ship fittings, gears, etc.), plastics, furniture, cables, clothing, and the production of food items, sterilized milk, and cigarettes. Schwerin is a railway junction and a focal point of roads.

Schwerin Bezirk extends northward from the Elbe to within about 12 mi. (19 km.) of the Baltic Sea, and is bounded westward by the Federal Republic of Germany. Area 3,348 sq.mi. (8,671 sq.km.). Pop. (1964) 593,722. The *Bezirk*, constituted in 1952 from parts of the *Länder* of Mecklenburg and Brandenburg, is divided into the urban district of Schwerin and ten rural districts. The other principal towns are Güstrow (*q.v.*), Wittenberge, and Parchim. The district is mainly agricultural (rye, sugar beet,

potatoes) with some forestry, and there is extensive peat-cutting on the outskirts of Schwerin town.

SCHWINGER, JULIAN SEYMOUR (1918–), U.S. physicist, shared the 1965 Nobel Prize for Physics with R. P. Feynman and S. Tomonaga (*qq.v.*) for their contributions to quantum electrodynamics. His independent work in the 1940s substantially contributed to methods for mathematically treating the behaviour of interacting elementary particles such as those encountered in the decay of radioactive materials (*see* PARTICLES, ELEMENTARY: *Renormalization: Dispersion Theory*). He was born in New York City on Feb. 12, 1918, and entered the City College of New York at the age of 14; he received an A.B. (1936) and Ph.D. (1939) from Columbia University. From 1939 to 1945 he served first as National Research Council fellow, then doing research and teaching (in order) at the University of California (Berkeley, where he worked with J. Robert Oppenheimer), Purdue University, and Massachusetts Institute of Technology. In 1945 he joined the faculty at Harvard University, where he served as professor of physics. Earlier (1951) he was the co-recipient of the first Albert Einstein Award.

Schwinger's publications include *Quantum Electrodynamics* (1958), a group of selected papers assembled under his editorship.

SCHWYZ, a town and canton in central Switzerland. The town, capital of the canton, lies at the foot of the Grosser Mythen (6,230 ft. [1,899 m.]), 16 mi. (26 km.) E of Lucerne and 3 mi. from Brunnen, its port on Lake Lucerne. Pop. (1960) 11,007, including the hamlets of Ibach, Seewen, and Rickenbach. The main buildings of interest include several 16th- and 17th-century patrician houses, the Baroque church of St. Martin (1769–74), the Kerchel chapel, the ancient St. Peter's nunnery (rebuilt 17th century), the historical museum, and the 17th-century town hall. The Archives (1935) houses the charter of the confederation and has a collection of old federal charters and banners; in its garden is the statue of "National Defense." Schwyz is a popular and picturesque summer resort, with a mild climate. It is the starting point for extensive mountain tours, and the well-known skiing regions of Ibergeregg, Holzegg, and Stoos are nearby.

SCHWYZ CANTON is one of the ancient Forest cantons of central Switzerland. Its total area is 351 sq.mi. (908 sq.km.), of which roughly three-quarters is reckoned as productive (forests covering about 75 sq.mi. and vineyards about 30 ac. [12 ha.]); of the rest, 20 sq.mi. is occupied by the larger lakes (chiefly parts of Zürich and of Lucerne, a small area of Zug and the whole of Lowerz). Pop. (1960) 78,048, mostly German-speaking Roman Catholics. Its loftiest point is the Böser Faulen (9,199 ft. [2,804 m.]), while two of the highest summits of the Rigi (the Kulm, 5,909 ft., and the Scheidegg, 5,453 ft.) are within its borders; but, on the whole, the land is hilly rather than mountainous. It has two main valleys, the Muota, receiving the waters of Lake Lowerz and draining into Lucerne, and the Sihl, which receives the Alp River on which Einsiedeln stands; the reinforced stream, though formed near the head of the Lake of Zürich, flows for a long distance roughly parallel to it and enters the Limmat River below the lake.

Schwyz is in the diocese of Coire. The largest town, after Schwyz, is Einsiedeln (pop. [1960] 8,792), a great pilgrimage centre noted for its Black Virgin and its Benedictine monastery. The canton is essentially pastoral, its local breed of brown cattle being much esteemed, particularly in north Italy, but there is some industrial activity (textiles) near the Lake of Zürich and Schwyz. The 30 cantonal communes are grouped into six administrative districts. The legislature (*Kantonsrat*) is composed of 105 members and the elections, since 1907, are carried out by proportional representation. The executive (*Regierungsrat*) of seven members is elected by popular vote and, like the larger body, holds office for four years. The two members of the federal *Ständerat* and the three of the federal *Nationalrat* are also chosen by popular vote.

The canton has few main railways, the principal one being a portion of the main Saint-Gotthard line between Sisikon and Küssnacht. Arth-Goldau (memorable for the great landslide of 1806) is a railway junction, with a line to Zug and another past Biberbrücke (junction for Einsiedeln) toward Wädenswil. A mountain railway also terminates at Arth-Goldau for the ascent of the Rigi Kulm. Of other mountain lines in the canton the most important are the electric cogwheel railway from Brunnen to Axenstein and the funicular from Schwyz to Stoos (4,265 ft.), the steepest in Switzerland.

History.—The valley of Schwyz is first mentioned in 972 as "Suittes." Later, a community of freemen settled at the foot of the Mythen, subject only to the count of the Zürichgau, as representing the German king. In 1240 the community obtained from the emperor, Frederick II, the privilege of being subject immediately to the empire. Its territory then included only the district around the village of Schwyz and the valley of the Muota. But in 1269 it bought Steinen and Rothenthurm. Schwyz took the lead in making the famous Everlasting League of Aug. 1, 1291, with the neighbouring districts of Uri and of Unterwalden (Obwalden-Nidwalden), its position and political independence specially fitting it for this prominence. An attack by Schwyz on Einsiedeln was the excuse for the Austrian invasion that was gloriously beaten back in the Battle of Morgarten (Nov. 15, 1315). In the history of the league Schwyz was always to the fore, so that its name in a dialectal form, Schweiz (Switzerland), applied to the three Forest cantons as early as 1320 and extended to the whole confederation by 1352, though it formed the official name only from 1803 onward. After the victory of Sempach (1386) Schwyz greatly extended its borders. An alliance with Einsiedeln in 1397 ended in 1434; between 1386 and 1436 the March (the region near the upper Lake of Zürich) was acquired; in 1402 Küssnacht was bought, and in 1440 the Höfe, the parishes of Wollerau, Feusisberg, and Freienbach, situated on the main lake of Zürich. All these districts were governed by Schwyz as subject lands, the supreme power resting with the *Landsgemeinde* (or assembly of all male citizens of full age). Schwyz joined the other Forest cantons in opposing the Reformation, and took part in the Battle of Kappel (1531), in which Huldreich Zwingli fell. In 1798 Schwyz, including Gersau (free from 1390), formed part of the République Telliane (or Tellgau), set up by the French, which a week later gave way to the Helvetic Republic. In 1803 the separate canton of Schwyz was again set up. Schwyz joined, in 1832, the League of Sarnen, and in 1845 the Sonderbund. In 1832 the outer districts (Einsiedeln, the March, Küssnacht, and Pfäffikon) formed themselves into a separate canton, which led to a federal occupation of the old canton in 1833 and to the dissolution of the new. In 1838 strife broke out in the older portion of Schwyz between the richer and poorer peasants over the use of the common pastures. The cantonal constitution of 1848 put an end to the ancient *Landsgemeinde*; it was revised in 1876 and in 1898. *See also* SWITZERLAND: *History; Administration and Social Conditions.* (P. Sc.)

SCIACCA, a coastal town and episcopal see in the province of Agrigento in southern Sicily. Pop. (1961) 30,596. Though the town has a modern appearance it retains some of its ancient fortifications: the town walls (*c.* 1550), the ruins of the castle of Luna (a Spanish family of the 15th and 16th centuries who were rival lords of the town with the Perollo family), and the Porta San Salvatore with 15th-century bas-reliefs. The 14th-century Steripinto palace and the 15th-century church of Sta. Margherita are of architectural interest. Sciacca is the birthplace of the historian Tommaso Fazello (1498–1570) and the painter Mariano Rossi (1731–1807). The town, occupying the site of the Roman Thermae Selinuntiae, is a thermal resort; nearby are the hot springs of Mt. San Calogero (ancient Mons Cronius).

(M. T. A. N.)

SCIATICA is pain along the course of the sciatic nerve, down the back of the leg. It often develops either immediately, or after an interval of several hours to a few days, following an unusual movement or exertion that places a strain on the lumbar portion of the spine where the nerve has its roots. The pain may be made worse by coughing and sneezing, and by flexion of the neck. It is relieved by positions that minimize traction on the sciatic nerve; for this reason a person with sciatica tends to walk with the affected leg bent at the knee and externally rotated at the hip. Sciatica is commonly associated with rupture of a portion of an intervertebral disc into the spinal canal. Most cases,

including those in which the nerve is displaced by protruding disc substance, can be treated effectively by bed rest on a firm mattress for several days to a few weeks. In some cases, however, surgical decompression of the nerve is necessary to prevent repeated attacks of disabling pain or to relieve serious, progressive disturbances in function of the sciatic nerve, which take the form of weakness and sensory loss in the leg.

Sciatica usually is a benign, if temporarily disabling, reflection of human structural imperfection. However, it may also develop as a symptom of some local compressive lesion other than a protruded intervertebral disc; or it may indicate a more generalized disorder involving the peripheral nerves (*see* NEURALGIA; NEURITIS). (S. SN.)

SCIENCE, HISTORY OF. This article treats the history of science under the following headings:

I. INTRODUCTION

Is it possible to define what is meant by science? Perhaps not, for science is one of the major activities of the human mind, in this resembling art, religion, or philosophy, which can be understood only in relation to their past history. Science may perhaps be regarded as a mood in which the world is considered. No man is always in the same mood, and no man of science remains permanently in the scientific mood. In evaluating the judgments of men of science outside their own department it is well to remember this, for these judgments are sometimes to be rated very low.

It is very difficult to discuss science as a whole. The Latin word *scientia* meant "knowledge," but the modern usage covers only certain kinds of knowledge whose area, however, is now so vast that no man can grasp more than a fraction of them. Moreover, "scientific" knowledge is extremely diverse, extending from subatomic reactions to mental processes; from mathematical laws of thermodynamics to the economics of race relations; from the births and deaths of stars to the migration of birds; from the study of ultramicroscopic viruses to that of extragalactic nebulas; from the rise and dissolution of cultures and of crystals to the rise and dissolution of atoms and universes. It includes both knowledge of the workings of living bodies and knowledge of the laws of thought, together with the nature of their disturbances. Can this great diversity of topics be brought under any one formula?

All involve systematic and unbiased observations. The examination of records of observations by trained minds leads to classification; from classifications general rules or "laws" are deduced; these laws may be applied to further observations; failures in correspondence between new observations and accepted laws may result in alterations of the laws; and these alterations lead to yet further observations; and so on. This is usually held to constitute the "method" of science. (*See* SCIENTIFIC METHOD.)

A short cut may, however, be taken by a mental process of which little is known; but even then the final appeal is to observation, often in the form of experiment. Further, science is always developing and is not a static body of knowledge. To summarize, science is a never-ending search for judgments to which the universal assent of experts may be obtained.

In English, as in other languages with vocabularies even more largely Latin-derived, the complex adjectival form of the word "science," namely "scientific" (*i.e.,* "knowledge-making"), has been steadily displacing simpler, shorter, and more natural formations, such as "sciential," "scientic," and their variants, since the beginning of the 17th century. The acceptance of the form "scientific" follows closely the growing prestige of what has come to be called "science" (earlier "natural philosophy"). This correlation of concept and adjective becomes intelligible in the light of the growing awareness that science is the making of knowledge and not knowledge as such, so that it has become more nearly equated with "research." When the process of making knowledge ceases, science subsides into static or recessive tradition. Science, nevertheless, does not exclude tradition, but necessarily involves developing tradition. It is, of course, true that atomic physics, for example, may be advanced without exact knowledge of the careers, achievements, and mental processes of Max Planck and Albert Einstein; and there are episodes of research wherein the researcher is wise to confine himself temporarily to his own thoughts. But the man of science inherits an age-old way of thinking; and only by extending knowledge previously won can he build new knowledge.

Despite their philosophical importance, controversies on the nature of knowledge, on the question of whether our knowledge is real or whether there is another and deeper reality to which we cannot reach, and the even more pressing debate as to how or whether science can give certitude are of no aid in defining, delimiting, or understanding the nature of science (*see* KNOWLEDGE, THEORY OF). Science can treat the outer world solely on the level of phenomena ("things that appear," "appearances"), which can appear only to the senses. The senses may yield results that are ultimately contradictory or in which, at least, the mind can find no harmony. But the quieting of the mind on such things is ultimately a task of philosophy or religion or both.

Yet by technological devices the sphericity of the earth, the discontinuity of matter and of forces, the movements of atoms, the bending of light by the sun's mass, and even the mutual convertibility of mass and energy may be demonstrated to the senses. Although it is true that science frequently leaves phenomena altogether, to mount into an atmosphere of abstract symbols, usually mathematical, it then descends again to the prediction or demonstration of phenomena. Phenomena must ultimately be sensed, and mathematical considerations, however recondite, and scientific instruments, however intricate, are but delicate, remote, and specialized ways of extending sense-experience, though sense-experience may for some sciences (and perhaps eventually for all) be ultimately reducible to scale readings.

II. THE AGE OF ANONYMOUS SCIENCE

Perhaps 400,000 years ago the weapons or tools of primitive men began to assume a symmetrical form involving some mental image of the object before it was wrought. This implied an adaptation of means to ends, based primarily on trial and error, a form of experiment used even by lower animals, but for men, a great step on the road to science. About 30,000 years ago men succeeded in portraying animals in positions of movement. A further passage to exact observation and the recording of nature occurred when they became food growers about 13,000 years ago. Sowing and reaping times were chosen according to the lunar and solar cycles (*see* CALENDAR: *Primitive Calendar Systems*). Numbering of days became necessary with city life. More settled agriculture needed specialized tools, and technology began to develop.

The age of stone passed into that of metals, which involved treatment of ores, extraction, and working. The development of rights in land demanded surveying: tradition has it that the an-

nual Nile flood rendered necessary an annual remeasurement of the fields of Egypt. Thus geometry (literally "earth measurement") was born. The cutting up of animals for food and the examination of their entrails for divination yielded, especially in Mesopotamia, some knowledge of bodily structure. These activities are among the sources of metallurgy, mathematics, and anatomy.

As society became yet more complex, commerce increased. The stewards and priests of palaces and temples needed records, so that systems of numerical notation were invented; and ultimately writing developed from pictographs.

Investigation of the ancient empires, notably the Babylonian, has revealed a far more extensive and systematic accumulation of astronomical and mathematical information than was formerly suspected. Science can therefore no longer be called a Greek product. Cumulative records began in the 4th millennium B.C. in the river valleys of both Egypt and Mesopotamia: but those that have survived are so discontinuous that the history of science in these ancient empires still cannot be written. *See,* however, CALENDAR: *Egyptian Calendar; Babylonian and Assyrian Calendars.*

(C. SI.)

III. INDIAN SCIENCE

1. General.—The scientific movement that originated in India spread widely. Its writings consisted of numerous treatises, commentaries, manuals, and technical dictionaries, which, in translation, gave rise to new movements in other parts of the East. In the West, it influenced and was influenced by the traditions of western Asia and Greece. It was based on rational principles in the sense that it sought natural explanations for observed phenomena and on a theoretic logic against which ideas were tested. The oldest Indian texts, older than the known scientific treatises, are already preoccupied with man and the external world and are almost devoid of magic, so much in vogue in other contexts.

Indian science concentrated chiefly on astronomy, physiology, and psychology; it neglected physics, geography, geology, and zoology. It made great progress in plant knowledge; but less in order to understand plants than to list their properties for food, medicine, or technical use. It composed (somewhat late) a chemistry which is mostly alchemy or materia medica.

Although Indian science speculates rationally, seeks detailed knowledge, observes, and forms explanatory hypotheses, rarely does it experiment, except in psychology, where it made its greatest progress thanks to its techniques of body and mind control. Elsewhere its theories were founded on insufficient facts, owing to its exclusively practical purpose in observation and lack of systematic and exact research. The theories gave mental satisfaction but were not fitted to a superficially regarded reality. This intellectual satisfaction, allied to a withdrawal within its ancient heritage while India was under foreign domination, eventually arrested the progress of science after a long period of brilliant development. But its tradition of study and logic was not destroyed, and modern India has adapted this intellectual inheritance to current international research.

2. Beginnings of Cosmogony and Astronomy.—The ancient Brahmanic and Vedic texts frequently refer to a general concept of natural law, Good Order, or Norm: the so-called *rta.* To it is opposed the *anrta,* the "Not-Good-Order." (The Old Persian *arta,* Avestic *asha,* shows this idea in Indo-Iranian prehistory.) This Good Order, later to be called *dharma,* the right ordering of all things, is universal, being cosmic, social, and moral. The universe shows forth the *rta* by the regular progress of the stars and the cycle of the seasons, especially the rains, upon which all life in India depends. Ritual ceremonies must be regulated by the Good Order of nature, so as to maintain or increase the prosperity of king and people. Hence the seasons and the positions of the heavenly bodies were early recorded on an approximately exact, luni-solar calendar (*see* CALENDAR: *Hindu Calendar*).

The religious texts correlate heavenly bodies and deities, but do not forecast human destiny by the stars. They explain certain astronomical phenomena by mythical stories eventually seen to disagree with observation; *e.g.,* that of King Moon, going into a "decline" on account of the complaints of his wives, the constellations, who take exception to his devotion to one of them at the expense of the rest—while the calendar records the moon's uninterrupted passage through each constellation in turn.

The Brahmana texts state that the world was created by the Word of the Veda, and assimilate the number of Vedic stanzas to that of the "moments" (*muhurta*) of the year, *i.e.,* 10,800 (30 moments a day $\times$ 360 days), the number of syllables in the stanzas amounting to 432,000 (this being also the number of years of the cycle of the universe called *kali yuga*). These numbers, or their submultiples or decimal multiples, were interpreted as the key numbers of the heavenly revolutions and of the laws of the universe and were therefore preserved in classical astronomy. Indeed, $108 = 27$ (basic number of *nakshatras*) $\times$ 4 (number of moon's phases); and $432 = 27 \times 16$ (number of portions of the lunar half-month). (*See* CHRONOLOGY: *Hindu.*)

The Vedic texts explain human and animal life by the circulation of breath (*prana*) in the body (see *Medicine,* below). These texts call doctors unclean, which shows that they originated in different regions from those where the *Ayurveda,* "science of longevity," was elaborated. (*See* MEDICINE AND SURGERY, HISTORY OF: *Traditional Medicine and Surgery in the Orient: India.*)

3. Early Mathematics.—The beginnings of mathematics are unknown; but the sacrificial formulas of the *Yajurveda* (*see* SANSKRIT LITERATURE: *Vedas*) bear witness to the use of high numbers among special names (up to *arbuda* = 100,000,000). The oldest mathematical texts are aids to Vedic religious ritual, and deal chiefly with the building of the *vedi* (sacrificial platforms) and the *citi* (heaps, tumuli, altars). The *Yajurveda* lists the kinds of altars, but it does not follow that the manuals are contemporary with it, for the geometrical problems solved in them apply to modifications (possibly later) of the buildings. Conversion theorems for figures concerning fixed proportions are given; and, in particular, the theorem of the square of the hypotenuse of a right-angled triangle and the sum of the squares constructed on the other sides is expounded. The texts belong in general to the high period of Vedic ritual (1st century B.C.).

4. Classical Mathematics and Astronomy.—Mathematics other than ritual geometry was mostly linked with astronomy; and from the first centuries A.D. astronomical treatises generally included mathematics. (However, the manuals of Mahāvīrācarya, 9th century, and Mallanna, 11th century, were for calculation only. The Bakhshali manuscript from Kashmir [*c.* 12th century] is a collection of arithmetical problems and solutions.)

The astronomical treatises contain astrology. From about the 4th century B.C., especially, the notion of sidereal influence on mankind is evidenced by proper names; *e.g.,* Candragupta, "the Moon's protégé," Brhaspatimitra, "Who has Jupiter for friend." But other names, such as Agnimitra, "Who has Fire for friend," imply that the planetary divinities were no more than protectors like the rest. Astrology properly so called appears in the first Christian centuries, with phonetically transcribed Greek terms in the Sanskrit texts. Its vast literature utilized the findings of scientific astronomy, on which there survive classical treatises and summaries of and allusions to lost treatises.

Classical tradition is represented, first of all, by the (lost) *siddhanta* "solutions" (Arabic *Sindhind*) of Paitamaha (Brahman), Vasistha, Paulisa (Paulus Alexandrinus), the Romaka (*i.e.,* Roman), and Surya (the Sun), the most important being the last named. They are known from a description and critique of their main data in the *Pañcasiddhantika* of the astronomer-astrologer Varaha-mihira (6th century A.D.). The chief works by individual authors are the *Aryabhatiya* ("[the work] of Aryabhata," whose author was 23 in A.D. 499 and wrote about the beginning of the 6th century); Brahmagupta's *Brahma-sphuta-siddhanta* (A.D. 628; *see* BRAHMAGUPTA); and Bhaskara's *Siddhantasiromani* (1150; *see* BHASKARA). These are not in a uniform tradition. Aryabhata stands apart especially in accepting the rotation of the earth on its axis. All consider time to be an indefinite cycle of "great yugas;" *i.e.,* periods at the end of which all the planets will return to the same position after a whole number of complete simultaneous revolutions. The 12-sign zodiac (*q.v.*) also appears now. (*See* CHRONOLOGY: *Hindu.*)

Astronomical tables were condensed into verse; and this led to the invention of several methods of expressing figures in words with a numerical value or in letters and combinations of letters (*see* ALGEBRA, HISTORY OF). The shifting of figures in position to signify their change of value and the use of zero in the form of a special sign or a space were known to Babylonia (in the sexagesimal system) before India; but India came first with decimal numeration and the notation of numbers with nine figures and zero (or gap). From India this system spread to the Arabs and the West (*see* MATHEMATICS, HISTORY OF). It is implied in Aryabhata's work by his method of extracting square roots. Trigonometry appears with the substitution (from the *Suryasiddhanta* and in Aryabhata) of the half-chord of the double arc for the chord of an arc (*see* TRIGONOMETRY: *History*). Aryabhata gives rules like: the product of two factors equals half the difference between the square of their sum and the sum of their square. Brahmagupta develops algebra as a general method for finding whole solutions to indeterminate equations of the second degree. The highest development is reached with Bhaskara, who devotes the first two parts (*Lilavati* and *Bijaganita*) of his work on astronomy to arithmetic and algebra, and who breaks down complex movements into uniform, instantaneous, combined movements. In the 18th century, a Sanskrit version of an Arab translation of Euclid was made for Maharaja Sawai Jai Singh II of Jaipur (1699–1743). Jai Singh also investigated European astronomy and built in the north of India several great observatories with huge instruments made of masonry (Jaipur, Delhi, Mathura [Muttra], Benares [Varanasi], Ujjain). The gnomon and the clepsydra had been, on the whole, the essential tools of ancient astronomy. Classical astronomy also used the armillary sphere and various circles, half-circles and quarter-circles. Bhaskara invented an astrolabe (*phalakayantra*).

5. Medicine.—Classical Indian medical knowledge is called *Ayurveda*, "knowledge of long life," the two chief traditions being those "of Atreya" (6th century B.C.) and "of Dhanvantari." The most important recension of the former is the *Agniveśatantra*, held to have been prepared by Agniveśa, one of Atreya's pupils, and edited by Caraka (possibly the Charaka who was doctor to the Indo-Scythian king Kanishka, *c.* 2nd century A.D.). This edition, the *Caraka Samhita*, includes some later additions. The Dhanvantari tradition, revised and completed by a certain Nagarjuna believed to be the Buddhist philosopher of this name (2nd–3rd century A.D.), is represented by the classical *Suśruta samhita* (named for Dhanvantari's disciple Suśruta), its present form dating from the first Christian centuries. The *Suśruta samhita* stresses surgical teaching and the *Caraka Samhita* diagnosis and prognosis. These works are the basis of a Sanskrit medical literature, some of which was translated into Tibetan and some from Tibetan into Mongolian. The *Rgyud bzi*, or "Four Books," is still popular in Tibet.

Such literatures exist in other Indian languages, especially Tamil, whose chief medical works, in the classical tradition, are attributed to Agastya and Teraiyar. Two other fashionable medical traditions of South India are that of the Sittar or "Perfect Ones," containing an adumbration of chemistry; and *yunani* or "Ionian" (*i.e.*, Greek) medicine, transmitted through the Arabs and used by the Muslims.

Theoretically, classical medicine consists of: (1) general surgery; (2) eye, ear, nose, and throat treatment; (3) general therapeutics; (4) science of disease-causing demons; (5) child care; (6) antidotes; (7) strengthening or restoration of youth; and (8) aphrodisiacs. But the great treatises rarely follow these divisions. First they comprise a general section consisting of discussion of a doctor's qualifications and of the various methods of healing. Then they deal with the occasions of falling ill; the body (*i.e.*, anatomy and embryology); and healing procedures. Most have supplementary treatises, such as Suśruta's *Uttaratantra* on ophthalmology. Caraka has, for example, the *Indriyasthana* on the sensory and motor faculties. The great medical texts are unsystematic collections of teachings, as is shown by their title of *samhita* ("collections").

Their doctrines, however, are coherent. The body is made up of a combination of the five great elements of nature in order of decreasing density: earth, water, fire, wind, and empty space. Earth and space, represented by the "full" organs (*e.g.*, the liver) and "hollow" organs (*e.g.*, the stomach), are inert but animated by wind under the form of breath; by fire under the form of bile (to "cook" food by digestion); and by water under the form of phlegm. These three elements (*dhatu*) cause illness when they are overexcited or inhibited. The body, circulated throughout by them, is composed of seven other elements also called *dhatu*, which result from combinations of different proportions of the world's raw materials. These are: (1) chyle; (2) blood, which is chyle dyed red by fire (*i.e.*, bile); (3) flesh; (4) fat; (5) bone; (6) marrow; and (7) sperm. All possess the vital juice of energy, centred in the heart.

Wind, or breath, has five forms: "in front," to assure respiration and swallowing; "going upward," to produce speech; "concentrated," to blow up the digestive fire; "diffused," to move the limbs; and "going downward," to assure excretion and childbirth. Bile and phlegm, too, each take five forms, heating and illuminating for the bile, lubricating and binding for the phlegm.

Anatomy shows acquaintance with bones, joints, and muscles but imperfect knowledge of the internal organs, although rudiments of dissection can be seen in the examination of corpses steeped in running water. Great importance is attached to the vital organs and large agglomerations of blood vessels and nerves. The heart is the seat of the spirit (*manas*), toward which the sensory impressions converge under the impulse of the breath. Classical physiology is thus essentially pneumatist.

Temperament and bodily functioning are determined by the predominance of one of the three elements and by climate, the seasons, behaviour, and diet. Sickness (apart from wounds, drownings, or diabolical possession, especially in children) is due to bodily changes, chiefly in the three organic elements, caused by stress. The medical texts hardly envisage supernatural or determinist causes of illness. For example, according to Caraka, smallpox is caused by a perturbation of bile and phlegm and not by a malignant goddess, as popular belief would have it.

Pathology classes maladies comprehensively according to the symptoms. There are fevers, skin affections, urinary troubles, sugar urine (*i.e.*, diabetes), etc. Within these broad classes, forms of illness are distinguished according to the signs of perturbation of this or that element. Diagnosis, therefore, is more of the underlying disturbances provoking the illness than of the illness itself.

Healing seeks simultaneously to cure symptoms, to abolish causes, and to reestablish, by exciting or calming medicines, the normal relations of breath, bile, and phlegm. For this, hygiene, correct diet, and drugs (mostly vegetable) are very important. Pharmaceutical preparations are powders, pastes, steepings, decoctions, infusions, etc.; doses are taken in water, oil, or butter. Decongestants, leaching, blistering (by caustics), fomentation, blasting with vapours, and bringing on of sweats are separately classified. Fumigation and inhalation apparatus, surgical instruments, and bandages are fully described. Surgery is practised mostly on limbs, but includes daring operations such as trepanning, removal of cataract and hernia, grafting, and even sutures of the bowels, these last being done by bringing together the edges of the wound and putting on ants to bite them, pulling off the ants' bodies, and leaving their heads behind.

Caraka studies in great detail the conditions affecting validity of the doctor's observations, diagnoses and prognoses, and procedures. Rational though his writing is, however, even to having the air of a treatise on logic, he admits methods of forecasting the course of an illness which are pure divination; *e.g.*, interpretation of dreams and of omens encountered by the physician on his way to the patient. (This would seem to be due to Persian influence in the west of India previous to the 4th century B.C.) On the other hand, he accounts for premonitory dreams of death, for example, by perturbation of the three elements.

Veterinary medicine for horses and elephants is based on the same principles.

New methods of diagnosis and treatment developed. The examination of the pulse, for example, became a complicated method of interpreting disturbances of health. But medicine owed most of its enrichment to chemistry and psychosomatic

techniques, which developed outside the classic tradition.

6. Chemistry and Alchemy.—Some chemical preparations are prescribed by Suśruta and Caraka. The remarkable early development of metallurgy is attested by the renown of Indian iron, an example being the pillar of almost pure iron at Delhi with an inscription of the 4th century A.D.

Caraka sketches a theory of chemical reactions in connection with the tastes (acid, salty, etc.), which distinguish substances, and can combine or neutralize one another.

Chemistry texts properly so called begin with the *Rasaratnakara* attributed to the Buddhist sage Nagarjuna, whom several traditions describe as an alchemist. There are numerous medieval and modern texts. Some treat of the preparation of medicines, others of definitely alchemical matters such as the elixir of life, transmutation of metals, etc. Mercury and its salts play a key role in all these processes. There are "great essences" (chiefly cinnabar; *i.e.*, red mercuric sulfide), which are bodies in their natural state; and "lesser essences"; *i.e.*, metals and salts. Chemical procedures are chiefly extractions, purifications, and calcination. The efficacy of medicines is increased by repeated intense heating in a closed vessel. Percolated and organic substances (*e.g.*, vinegar, urine) are often used as solutions.

There were other chemical traditions in southern India (not exclusively related to the Sanskrit ones), which survive in Tamil texts.

Physics and zoology were neglected, physics being chiefly represented by atomist philosophical theories of the universe (*see* INDIAN PHILOSOPHY: *Six Systems*).

7. Psychology and Psychosomatic Techniques.—The most original and advanced Indian science was psychology, which made use of psychical and physiological techniques, *i.e.*, yoga, for the achievement of mastery over mind and body.

The analysis of the workings of feeling and thought begun in the last centuries B.C. (Upanishads and old Buddhist texts) resulted both in an idea of the importance of subconscious life attested by memory and in a realization of the link between bodily and psychic functions. Every conscious experience leaves a trace in the soul. These traces are not lifeless imprints but come together in "psychic constructions," which in turn form an ethereal body within the physical one. This ethereal body governs the tendencies and reactions of the soul, and can be reincarnated after death in a new physical body corresponding to the tendencies animating it. The direction of its development could be controlled by the yoga-regulated selection of its experiences. Yoga techniques consist in discipline of the attention, neutralizing external impressions; fixity of meditation; the placing of the conscious mind in a chosen attitude; and finally the setting up of corresponding "constructions" in the unconscious mind. To achieve this the yogin calls on physiological techniques which facilitate fixing of the attention and neutralization of external impressions; makes use of postures, attitudes, exercises, and, above all, breath control. This last is of special importance, partly because of the pneumatist theory of physiology, and partly through experience of the effect of control on heart rhythm and psychosomatic functioning. In addition, some forms of yoga borrow ideas about the vital points (*marman*) from the *Ayurveda*. These points are referred to a theoretical anatomical form related to the movements of breath in the body during the exercises and to symbolical correspondences between microcosm and macrocosm. (*See* also YOGA.)

8. Spread of Indian Sciences.—The Indian sciences very probably had links with Greek science in Persian Achaemenid times (559–330 B.C.). The *Hippocratic Collection* mentions some Indian medicines: it also contains a treatise "On the Winds," which expresses classical Indian ideas. In astronomy, calendar durations decided upon by Heraclitus and the Babylonian Berossus correspond to Indian values. Indian science mostly spread, however, to Tibet, China, Japan, Indochina, and Indonesia. The astronomical system of *nakshatras* (constellations of the ecliptic entered by the sun and moon) is balanced by the 12-year zodiacal cycle of Jupiter used by the Chinese (*see* CALENDAR: *Chinese Calendar; Hindu Calendar*). Ill-defined relations existed between the Chinese and Indian alchemical systems. The medical sciences were not related; but some of the Taoist techniques for breath regulation and control of body and thought seem to have been influenced, if not inspired, by yoga brought to China in parallel with Buddhism. (J. L. A. F.)

IV. CHINESE SCIENCE

1. General.—The beginnings of Chinese science were contemporaneous with and parallel to those of Greek science, but soon developed the characteristic conceptions of correlation, association, and intuitive interconnection of the elements of the cosmos.

According to the Neo-Confucianist principle, the *Li* ("law," "reason") (*see* CHINESE PHILOSOPHY), all phenomena and all existing objects are like the contents of a basketmaker's shop, in which individual elements are without interest and only the finished product matters. The harmony of the universe results from the correct interrelationship of its parts. Thus, whoever knows the world (the macrocosm) knows man (the microcosm) by analogy.

The idea of the hierarchical order of the elements resulted in a construction which was completely arbitrary, but of such ethical, aesthetic, and cultural value that scientific progress was almost inconceivable.

Chinese science did not spread as did Indian, Greek, and Arab-Persian science. It has even seemed to be isolated; but in fact it was constantly enriched by foreign contributions and in turn exported its techniques (though not so much its speculations) to the West, from the 3rd century B.C. (Han dynasty). There was direct contact with Europeans from the 16th century. But the acquisitions of Chinese science from elsewhere were not equal to those of Arab science from Greek.

2. Astronomy.—Astronomy was not clearly distinguishable from astrology and was much more important for social and political life than as a science. The sovereign, at the centre of space and time, binding heaven and earth together, ruled over the cosmic order by imposing his calendar upon his subjects, just as his Western counterparts imposed their coinage.

The calendar was luni-solar. The shell oracles of the Yin dynasty (1st millennium B.C.) show that the solstices (recorded on gnomons) defined the limits of the year, just as the moon defined the month. To make lunar and solar periods agree, a fictitious intercalary month was inserted every third civil year. Thus the Metonic cycle, a 19-year period containing seven intercalary months, was discovered. (*See* CALENDAR: *Chinese Calendar.*)

The perfecting of the calendar, especially for forecasts of eclipses and other spectacular phenomena, was the chief aim of Chinese astronomy.

The chief instruments were the gnomon and the clepsydra or water clock. There were also armillary spheres and celestial panoramas moved hydraulically to reproduce the movement of the heavenly bodies. The toothed-wheel mechanism (for astronomical clocks) was discovered in the 11th century A.D. by Su Sung (1020–1101). Chinese astronomers distinguished the equator from the ecliptic; determined the length of the tropical year as distinct from the sidereal year; learned the precession of the equinoxes; observed sunspots and eclipses; and made star maps and catalogues.

The astronomer Kuo Shou-Ching (1231–1316) may perhaps have invented spherical trigonometry.

3. Mathematics.—Spills and the abacus were used for calculation. A group of spills, arranged vertically or horizontally on a flat surface, represented each figure. Errors in calculation could result from accidental displacement, however. The abacus (*q.v.*), being steady, was better (forms of it are still used in Asia and eastern Europe, great speed in calculation being attainable). Multiplication tables were used at least from the 6th century B.C. The calculating book of Sun Tzu (*Sun-tzu suan-ching*) is a manual of logistics believed to be of this period, containing a multiplication table from nine times nine to one times one. A manuscript in the Bibliothèque Nationale in Paris, brought to France from Tun-huang by Paul Pelliot (1908), gives a fragment of table; another, also from there, contains a Tibetan translation of a frag-

ment of Chinese table. Such tables were necessary on account of the extreme accuracy required for the use of both spills and abacus, for numbers had to appear in succession and workings-out could not be recorded.

Chinese mathematical works were compilations for the solution of the practical problems of engineering, business, and administration. Rare were the true scholars to whom mathematics was an end in itself; as can be seen from Chinese treatment of the Pythagorean theorem and the calculation of π.

The first part of the *Calculating Book of the Gnomon* (*Chou-pei-suan-ching*), 5th–3rd century B.C., applies Pythagoras' method to the right-angled triangle with sides 3, 4, and 5; and the method seems to have been thought of as a practical procedure rather than as a theorem.

Another portion of the *Calculating Book*, composed about the 2nd century B.C., uses the number 3 for the value of the relation of circumference to diameter; this value is again discussed in the *Nine Chapters on the Mathematical Art* (*Chiu-chang suan-shu*), with commentary by Liu Hui (*c.* mid-3rd century A.D.). Liu Hui uses the method of inscribed polygons, and obtains the number 3.14 with a polygon of 192 sides. A 5th-century astronomer and mathematician, Tsu Chung-Chih, would seem to have calculated π with six decimals and to have obtained an excellent approximation (π between 3.1415926 and 3.1415927); but the work believed to be his was lost about the 10th century.

The Chinese algebrists of the second half of the 13th century were perhaps the world's greatest. Chu Shih-Chieh (*c.* 1299) outdid all his predecessors, anticipating Pascal, Leibniz, P. Ruffini, and W. G. Horner; only to be forgotten.

Modern Western scholars find that Chinese mathematics, despite its strongly archaic character, can enrich modern mathematics with forgotten perspectives and new attitudes.

4. Physics.—There was much stress on acoustics, because of the political and social importance of music in ancient China. The pitch standard ("yellow bell," *huang-chung*) was a bamboo flute. This standard served also for the sound wavelength. With it, Prince Chu Tsai-Yü discovered the equally tempered scale about 1595 (*i.e.*, before M. Mersenne [1636], J. S. Bach, and J. P. Rameau). He also left a treatise on time and a perpetual calendar (1584).

5. Chemistry.—Chemistry never succeeded in freeing itself from alchemy, which began in the 4th century B.C., culminated during the 2nd and 3rd centuries A.D., and decayed from the 14th to the 17th centuries. Its relations with the other alchemical systems of Europe and Asia are ill known. Ko Hung (*c.* 281–340) was head of a scientifico-mystical school which sought potions of longevity and immortality (not for the philosopher's stone). Their adumbration of natural philosophy, had it been better exploited, could have helped the development of science and technology, as witness *The Exploitation of the Works of Nature* (*T'ien-kung k'ai-wu*, 1637). (*See* also ALCHEMY; TAOISM.)

6. Natural Sciences.—In geology, knowledge of natural gases, oil, mineral deposits, and fossils ("dragons' bones") is very ancient. Chang Heng built (A.D. 132) the first known seismograph, and earthquakes were recorded very early.

Botany was highly developed; China's vegetation was rich and many useful foreign plants were imported. The first botanical gardens appeared during the Han dynasty. Li K'an published a *Treatise on Bamboo* (*Ch'u-p'u hsiang-lu*) *c.* A.D. 1299. The study and drawing of vegetables is older and is a topic of numerous treatises. Gardening flourished from T'ang times (7th–10th centuries A.D.), when new varieties of flowers were obtained by selection and grafting.

There were treatises on zoology too; and animals studied included the unicorn, phoenix, and dragon. The Chinese had little gift for rearing mammals (except for Pekingese dogs), but showed remarkable skill with insects, mollusks, fish, and birds. They also raised bees, silkworms, and crickets (for fighting). From the 10th century A.D. they bred fish, creating new varieties from goldfish. In the 13th century they tried to obtain artificial pearls. Lastly, they used birds as messengers (pigeons), fishers (cormorants), hunters (falcons), for fighting (quails, cocks), and as pets.

7. Medicine.—Medicine was based on the two principles of the elements and the vital breaths. There were 12 paired, symmetrical vessels (canals); linking organs and viscera, and continuously circulating the vital breath, the blood, and the *yin* (female principle) and the *yang* (male principle). The Jesuit translators equated these last with Galen's moisture and warmth.

Illness was diagnosed by inspection, examination of the tongue, and, above all, study of the pulse. Measles, smallpox, beriberi, rickets, scurvy, and goitre were thus identified; their causes were traced and they were treated by diet. Certain skin diseases also were known (scabies, leprosy, syphilis). Dietetics and hygiene were highly developed, although for centuries they served the illusory purpose of helping to secure immortality.

In sex, the "bedroom treatises," from the Han dynasty onward, distinguished between ordinary intercourse with the aim of impregnation and *coitus reservatus*, in which the man controls his genital reflexes so that he does not ejaculate.

The extremely rich body of medical materials is expounded in the *Pen-Ts'ao*, exhaustive studies of mineral, vegetable, and animal products, used for medicine, pharmacology, biology, dietetics, chemistry, industry, folklore, history, geography, and even philology. The most famous is the *Pen-Ts'ao Kang Mu* of Li Shih-Chen (1518–93), the only important 16th-century work outside the system of Galileo and Vesalius. In modern China and Japan, the *Pen-Ts'ao* are the subject of a flourishing science (pentsaology).

Ancient Chinese treatments included moxibustion (cauterization by wormwood leaves), acupuncture (*q.v.;* needle puncture acting on the 12 canals), movement therapy, breathing and relaxation techniques; all of which are of renewed interest to modern medicine. *See* also CHINA: *History*. (P. HU.; M. WO.)

V. GREEK SCIENCE

1. Beginnings and the Classical Period (*c.* 600–*c.* 300 B.C.).—The figure traditionally associated with the beginning of science among the Greeks is Thales of Miletus in Asia Minor, who flourished in the first half of the 6th century B.C. He made certain geometrical discoveries, though the elements of geometry, according to Greek tradition, came from Egypt (and those of astronomy from Mesopotamia). The Egyptians, however, had not generally reached beyond an empirical use of certain special relations of such figures as triangles and rectangles, pyramids and spheres. The question as to how far they generalized mathematical conceptions is still under discussion. On the other hand, there is evidence from their art that they knew and constantly practised the "golden section." Thales or his Greek contemporaries succeeded in generalizing such cases and made other discoveries in elementary mathematics.

By the 6th century B.C. Greek-speaking peoples had founded colonies in southern Italy and Sicily, whose intellectual activity, especially that of Pythagoras and his followers, was significant for science (*see* PYTHAGORAS AND PYTHAGOREANISM). The use of letters to express numbers by Phoenicians, Hebrews, and Greeks encouraged the Pythagorean belief in the independent existence of numbers and their mystical and magical application. It was the Pythagoreans who gave to the word "mathematics"—which first meant simply "learning"—its special relationship to number. Their conception of numbers as the elements of all things and of the heavens as a numerical and musical scale gave to science the important conclusion that there is a correspondence between the working of the human mind and the working of nature; and their doctrine of the relation of the four elements of matter to the four "humours" composing the human body was the first attempt to trace the rules of the external world to the working of man's body. By the middle of the 5th century B.C. the Athenian school of thought was commencing the specialization thenceforth characteristic of science, in the form of recognition of the independence of mathematics and medicine. Exemplars of this tendency were the geometer Hippocrates of Chios (*c.* 460 B.C.) and Hippocrates of Cos (fl. 400 B.C.), known as the "father of medicine." (*See* also MEDICINE AND SURGERY, HISTORY OF: *Early Greek and Roman Medicine.*)

The intellectual history of the 4th century B.C. is filled by the

gigantic figures of Plato and Aristotle, who are considered here only in their relation to science.

Many of Plato's thoughts assume a mathematical guise, and he thought that other studies should conform to the certitude of mathematics. He highly esteemed astronomy, regarding the motions of the heavenly bodies as perfect geometric forms; and for his followers astronomy became a field for the exemplification of mathematics rather than (as today) for its application.

Plato regarded the mathematical form of the universe as evidence of the rational mind of its Creator. "God," he is said to have said, "ever geometrizes." To deny the existence of mind as a separate entity was, he held, to assume the universe to be the result of accident, which was a denial of the validity of philosophy. It is not inconsistent with this view that Plato respected Hippocrates the physician, who "was the first who separated science from philosophy." But the trend of Platonism in general and of ancient Platonism in particular was usually away from observational activity, although there have been many evident exceptions, and Platonism has often been helpful to science both in stressing its quantitive aspect and in opposing an entrenched and static Aristotelianism. It was from Pythagorean teachers that Plato derived the so-called "Platonic bodies," the five regular polyhedra which have equal sides and equal angles. Many centuries later mathematicians proved that the possible number of regular bodies is only five, and it was from a consideration of these bodies that Kepler developed the first unitary scheme of the universe (A.D. 1596).

Aristotle devoted his incomparable genius to systematizing and organizing the whole area of knowledge. His earliest and, from the modern scientific point of view, his best efforts were on biological topics. The whole of his science and indeed the whole cast of his mind was deeply influenced by his firsthand observations of living things. In his *Parts of Animals*, he sets forth his view of the relation between biology and "physics," the latter being for him a general description of the universe. He says:

> Of the things constituted by nature some are ungenerated, imperishable, eternal; others subject to generation and decay. The former are excellent beyond compare and divine, but less accessible to knowledge. The evidence that might throw light on them and on the problems which we long to solve respecting them is furnished but scantily by our senses. On the other hand, we know much of the perishable plants and animals among which we dwell. We may collect information concerning all their various kinds, if we but take the pains. (Somewhat paraphrased.)

Living things are for Aristotle the type of existence, and existence as a whole presents, for him, evidence of design. He attempted to analyze the nature of generation, of heredity, and of sex; and treated many other topics. There is a profundity in his biological thought which gives it a permanent value. He was a first-class observing naturalist in the modern sense. (*See* also BIOLOGY: *History*.)

Aristotle, like Plato, had Pythagorean tendencies, which he exhibits in his physical scheme. He emphasized the "perfection" of the circle and of the sphere, on which therefore the world is modeled. For him the heavens are a series of concentric, crystalline, mechanized spheres arranged round the earth as a central body.

The mechanical scheme of the universe set out by Aristotle and his successors suggests a series of geared wheels and may have been suggested to the Greeks through some such complex apparatus. It was the basis of mankind's theory of the universe for 2,000 years. It may thus be summarized: (1) Matter is continuous; (2) All mundane things are made up of four "elements," which in their turn manifest the four "qualities"; (3) Stars and planets move with uniform circular velocity, embedded in crystalline spheres, centred round the earth. Each sphere is subject to the influence of those beyond; (4) Circular, changeless, eternal movement is perfect order. It contrasts with the rectilinear movement which prevails on our changing and imperfect earth; and (5) The universe is limited in space and within an outmost sphere. It is unlimited in time, being subject as a whole neither to creation nor to destruction.

2. Alexandrian Science: First Period (300–30 B.C.).—For the 500 years after Aristotle the scientific centre of the world was Alexandria. There mathematics assumed a prominent position. Among its first exponents was Euclid (fl. 300 B.C.), whose *Elements of Geometry* determined instruction in the subject for the next 22 centuries. (*See* GEOMETRY.)

Another Alexandrian teacher, Aristarchus of Samos (fl. *c.* 270 B.C.), made the first scientific attempt to measure the distances of the sun and moon from the earth and their relative sizes. He estimated the sun as 18 times more distant than the moon (instead of more than 346 times). That he thought the sun far larger than the earth may have suggested to him that it was improbable that a large body would revolve round a relatively minute one. Anyhow, he held that the earth rotates, and revolves round the sun.

Hipparchus (fl. 146–127 B.C.), the greatest astronomer of antiquity, erected at Rhodes the first recorded observatory. He developed trigonometry, by which numerical calculations can be applied to figures drawn on either plane or spherical surfaces. He made numerous observations and collated the records of Babylonian and earlier Greek astronomers to see if astronomical changes had taken place in the course of the ages. These comparisons led him to his two brilliant conceptions of the precession of the equinoxes and of planetary movements. (*See* HIPPARCHUS.)

Anatomy and physiology became recognized disciplines at Alexandria. The first medical teachers of the school, contemporaries of Euclid, began the practice of dissecting the human body publicly. They compared its structure with that of animals and opposed both Plato and Aristotle by regarding the brain as the sole seat of the intelligence. They observed that arteries, unlike veins, pulsate, but did not ascribe this to the heart's action, thinking that it was an activity of the arteries themselves. They thought of the nerves as hollow and as conveyors of the hypothetical "nervous fluid." They distinguished between the main brain, or cerebrum, and the lesser, or cerebellum; observed the cerebral convolutions of both man and animals; and associated their greater complexity in man with his intelligence. Their experiments on animals led them to distinguish between the posterior nerve roots of the spinal cord, which convey sensations, and the anterior, which convey the motor impulses.

From about 400 B.C. the doctrine of atoms (rejected by Aristotle) was current in the Greek world. Later, though important philosophically, it had on the whole a retarding effect on Greek science despite some influence on Alexandrian anatomy and physiology. Some Alexandrian anatomists supposed that nonatomic "air," equivalent to pneuma (*see* below), is taken in by the lungs and passes to the heart, where it enters the blood and is changed into a peculiar kind of pneuma—the "vital spirit"—which is sent to the various parts of the body by the arteries. It is thus carried to the brain, where it is further altered into another pneuma, the "animal spirit." This, they believed, reaches different parts of the body through the hollow nerves.

One Alexandrian school considered the pneuma that circulates in the body to be ultimately drawn from the air, or world-pneuma. This assumption gave a physiological basis to the philosophical conception of the spirit of man as part of the world-spirit frequent in later writings of the Stoic school (*see* STOICS).

The biological work of the early Alexandrian Theophrastus (*c.* 372–*c.* 287 B.C.), a pupil of Aristotle, should be mentioned. His botanical writings are the best-arranged ancient biological treatises. Among his many acute and accurate observations is his clear distinction between monocotyledons and dicotyledons. Interesting too is his attempted distinction of sex in plants, successful only for palms. His splendid botanical works had a definite influence on modern biology.

The greatest of the Alexandrian school was Archimedes (*c.* 287–212 B.C.) of Syracuse, constantly recalled in the mathematical construction of the Archimedean spiral (*see* CURVES, SPECIAL: *Section 38*); in the mechanical construction of the screw of Archimedes (*see* ARCHIMEDES, SCREW OF) for raising water; and for his exposition of the doctrine of levers.

Perhaps the earliest existing work of Archimedes is *On Plane Equilibria*. It sets forth certain fundamental principles of me-

chanics as rigorous geometric propositions. The work opens with his famous "postulate": "Equal weights at equal distances are in equilibrium; equal weights at unequal distances are not in equilibrium but incline toward the weight at the greater distance." This postulate developed into the principle of the steelyard (*see* WEIGHING MACHINES), and led Archimedes in the end to the discovery of the centre of gravity in a variety of geometric figures.

Among the achievements of Archimedes is his method of measuring the areas of curved figures and surfaces, most simply expressed in the effort to "square the circle." His predecessors had broached the important idea of "limits"; Archimedes, however, employed limits systematically.

The principle is that a square can be inscribed within a circle, the sum of its sides being evidently less than the circumference and its area less than that of the circle. The number of sides can be doubled to make an eight-sided figure within the circle. The proposition remains true, however many the sides; but as their number is increased the discrepancy decreases. "In the limit," when its sides become no more than points, the polygon may be conceived as becoming the circle. Archimedes realized that this limit can be approached as nearly as we wish (*see* LIMIT).

Archimedes proved that the area of a circle is equal to that of a triangle of base equal to the circumference of the circle and of height equal to its radius, by finding the ratio between circumference and diameter. To do this he sought the limit approached by the sides of regular polygons both inscribed in and circumscribed on the circle. The limits for their ratio to that of the diameter he found to lie between $3\frac{10}{71}$ and $3\frac{10}{70}$. The latter has since been generally accepted as a good approximate value of the quantity known as π.

He applied a comparable process to other curves. In his treatise *The Quadrature of the Parabola* he brings both an inscribed and a circumscribed rectilinear figure into relation with a curve. The two rectilinear figures, as it were, compress the curve, one from within and the other from without, until they coincide with it. This procedure, together with the use of mechanics for solutions subsequently demonstrated by geometry, leads to the consideration of his extremely important treatise *The Method*.

For the most part, Archimedes, like other Greek men of science, gives his proofs but does not tell how he reached them. In *The Method*, however, addressing Eratosthenes (*see* below) he recalls the discoveries which he had sent to his friend on a former occasion and then says that he is now explaining how he made them.

The Method applies two principles: (1) that a plane figure may be regarded as an aggregate of an infinite number of parallel lines; and (2) that consideration of the respective weights of two plane figures, one curved and one rectilinear, may reveal the approximate area of the curved figure. The same process may be applied to demonstrate relationship between the volumes of solid curved figures considered as aggregates of an infinite number of parallel plane figures. It amounts to a practical solution of problems of the relation between areas or volumes by analysis, mechanical or other, after which the investigator returns to a synthetical mathematical process. He thus gains by experience some estimate of the solution before he seeks its demonstration.

An Alexandrian successor of Archimedes, Apollonius of Perga (fl. 220 B.C.), developed the knowledge of conic sections. The familiar terms parabola, ellipse, and hyperbola derive from him. The idea of conics was for more than 1,500 years a purely intellectual exercise, generations of mathematicians discussing the properties of these curves, which were not known in nature. Then in 1618 Kepler discovered that planets move in elliptical orbits. Surely here the human mind showed itself attuned to nature, whose ways it had unwittingly explored for all these ages.

Among the Alexandrian luminaries was Eratosthenes (*c.* 276–*c.* 194 B.C.), the greatest scholar of his age. His most important achievement was the measurement of the globe of the earth by an operation of beautiful simplicity (*see* GEODESY: *Early History*).

Having measured the earth, Eratosthenes considered the known parts of it. Here, like all his predecessors, he had self-imposed limitations, regarding the habitable world as wholly within the Northern Hemisphere and forming only about one-third of that. He considered the land surface of the world to be longer from east to west than from north to south and estimated the distance from the Atlantic to the Eastern ocean as 78,000 stadia (about 7,800 geographical miles) and the distance from the parallel of the Cinnamon land (Ceylon) to that of Thule as 38,000 stadia. As he estimated the circumference or equator at 250,000 stadia, Eratosthenes could also estimate the circumference at the parallel of the "Pillars of Hercules" (Strait of Gibraltar), which he knew was also that of Rhodes. This fundamental parallel (latitude 36°) passed through other important points—the westernmost point of Spain, for example, and the southern points of Italy and of Greece—and along the Taurus Mountains. Eratosthenes estimated the total circumference of the world at this parallel to be 200,000 stadia. All but 78,000 stadia of this was sea.

At right angles to the parallel of Rhodes, Eratosthenes determined a north-south line between Alexandria and Syene. This, produced northward, he regarded as passing through Byzantium and thence to the Dnieper River. Southward, he considered that it passed to Meroe and then along the Nile.

These fundamental lines, together with those on other parallels of latitude and lines of longitude, are sufficiently accurate for constructing an outline world map in which the Mediterranean area is recognizable.

3. Alexandrian Science Under the Roman Empire (30 B.C.–A.D. 200).—Despite the dominance of Rome, science remained Greek in spirit and language. It was finally synthesized by two pupils of the Alexandrian School, Ptolemy (fl. *c.* A.D. 140) for cosmology and geography and Galen (*c.* A.D. 130–*c.* 200) for anatomy and biology.

Ptolemy's *Almagest* was of the highest significance for later astronomical development. Its basic cosmic conceptions come from his predecessors but are expounded with the utmost skill. Ptolemy invoked epicycles to explain the movements and behaviour of the planets, employing them to resolve some errors and inconsistencies of Hipparchus. However, he retained eccentrics to explain certain elements in these movements.

Ptolemy possessed a series of astronomical instruments, the existence of which proves the high degree of mechanical skill evolved during generations in exact metalwork. Among his greatest achievements is the determination of the distance of the moon by parallax: the method is in principle that still in use. Ptolemy estimated the moon's distance to be 59 earth radii, which is not very far from the truth. Working on an eclipse method of Hipparchus, he estimated the sun, however, to be only 1,210 earth radii distant, which is one-twentieth of the truth. He had no way of estimating the distances of the lesser planets but followed tradition in accepting apparent speed as the main test of nearness. His scheme passed to the Middle Ages. (*See* PTOLEMAIC SYSTEM.)

Ptolemy's other great work, his *Guide to Geography*, was a product of knowledge brought to him by Roman imperial expansion. He developed his own manner of representing on a plane surface the curved surface of the earth. In his "projection" the parallels of latitude are arcs of concentric circles. Chief among the parallels are the equator and the circles passing respectively through Thule, through Rhodes, and through Meroe. The meridians of longitude are converging straight lines.

The great biological synthesis of antiquity was made by Galen, a native of Pergamum in Asia Minor. Galen studied at Alexandria but spent most of his active life in Rome. He elaborated a complete physiological scheme, generally accepted until modern times. Three kinds of pneuma or spirit are involved in addition to the world-pneuma or air. The basic principle of life was drawn from the air by breathing. Entering the body through the windpipe, it passes, Galen thought, to the lung and thence to the left ventricle of the heart, where it encounters the blood. His view of the changes that then take place in the blood was most ingenious and was based on experiments, but the errors that it involved remained current till the 17th century and beyond.

Galen's scientific works are among the most influential of all time. Nevertheless, he established no school and had neither disciples nor direct followers. On his death anatomical and physio-

logical inquiry ceased abruptly. Mathematical and mechanical research continued a little longer than biological, but they pass into a silver period in the 3rd century. For science in general the Middle Ages begin effectively about A.D. 200.

VI. MEDIEVAL SCIENCE

There followed a period well-nigh barren in positive scientific results until versions of the Greek scientific works appeared in Arabic in the 10th and 11th centuries and in Latin, mostly from Arabic, in the 13th and 14th. Though these later "Middle Ages" added little to the growth of scientific knowledge, they did something for its coherence and presentation. The Eastern and the Western share are here treated separately.

1. Islamic Science (*c.* 850–*c.* 1200).—In the West, science disappeared with the Latin Roman Empire. In the Greek-speaking Eastern Roman Empire, a disintegration began that was never arrested. Much valuable Greek scientific literature was, however, translated into Syriac, the language of the heretical Nestorian Christians. Between 750 and 850 these versions were revised and many others added. From 850 to 950 Nestorian translators at Baghdad rendered the Syriac versions into Arabic. This presentation of Greek science in Arabic is the primary source of "Arabian science," which left a deep impress on the Latin world.

The Arabic language and culture spread afar: to Portugal in the west, as far as China in the east, and over many degrees of latitude. The most characteristic Arabic scientific developments were in alchemy, in mathematics, in astronomy, and in medicine.

Alchemical is a term used to describe very diverse kinds of literature, most of it highly mystical. From Egypt, from Byzantium, and perhaps from China, however, Arabic-speaking "alchemists" derived many recipes and methods for industrial processes, and their experiments demanded special apparatus. The greatest Arabic-writing alchemist, Rhazes (d. *c.* 930), makes the earliest known suggestions for furnishing a chemical laboratory. Industrial technology and alchemical apparatus of Arabic origin had an important role in the rise of modern chemistry.

In mathematics, only the Greeks attained so high a standard as the Hindus. By the 9th century, the Islamic peoples were using the Indian system of numerical notation, the so-called "Arabic numerals." The most influential work propagating this was by the Persian Mohammed ibn Musa al-Khwarizmi (*c.* 825), from whose name the medieval word for arithmetic, *algorism*, was formed. The title of the Latin version of his *Algebra* is the first Western use of the word in the mathematical sense: it means "rectification," that is, transposition of negative terms of an equation to the opposite side. (*See* ALGEBRA, HISTORY OF.) The Arabs also considerably developed the geometrical and optical works of the Greeks.

Astronomy and astrology were constant preoccupations of the Islamic world (*see* ASTROLOGY; ASTRONOMY: *History of Astronomy*). They were specially developed in Spain, groups of experts in them being formed at Córdoba and at Toledo. The Toledan tables of positions of stars were drawn up in 1080, their authors seeking to replace the Ptolemaic by a strictly concentric system.

In medicine, as in alchemy, the first and greatest original Muslim writer was Rhazes, whose erudition was all-embracing. He made the first distinction between measles and smallpox. It is impossible to mention Arabic medicine without recalling Avicenna (980–1037; *see* MEDICINE AND SURGERY, HISTORY OF: *Arabian Teaching and the School of Salerno*), whose work was for centuries standard in Latin as it still is in Arabic. He was scientifically much inferior to Rhazes. The physiology and anatomy typified by him was a grossly deteriorated version of the Greek. The great Arabic contribution to medicine is the introduction of new vegetable drugs, many of which are still in use.

2. Science in the Latin West (1100–1450).—Until the 11th century no Western scientific movement needs consideration, since Spain in those earlier centuries was within the orbit of Eastern culture. In the 11th century the West began to come into relation with the East through Latin translations of Arabic works. These, during the following three centuries, came mostly from Spain but also from Sicily, from Provence, and from Syria.

Medieval Latin had at first no technical scientific vocabulary. The translators, therefore, often transliterated Arabic words, and thus many Arabic names of stars, of chemical substances, of apparatus, of plants, and even of anatomical parts passed into Latin. Some have survived in modern vernaculars. Moreover, Aristotle's views of the structure of the universe as conveyed in these Arabic-Latin translations from his works and from those of Ptolemy provided the medieval world-picture. The recovery of the works of Aristotle was a major factor in the 13th-century revival of intellectual coherence and gave to scholastic science its essential character. This "medieval Aristotle" was later modified by a slow infiltration of direct translation from the Greek.

Great emphasis has often been placed on medieval "forerunners" of science, notably on Roger Bacon (*c.* 1220–*c.* 1292); his scientific contribution was, however, small, as was that of several other medieval writers who sought to outline a philosophy of science. There were experiments with the compass (perhaps under Arabian influence); the problem of the path of light within a spherical lens was partially solved on a mathematical basis; a parabolic burning mirror was constructed or at least attempted; and a solitary genius made a workable astronomical clock of great complexity. But these achievements, scattered over two or three centuries, are minute compared with those of the best Greek or Arabic centuries. They hardly justify a revision of the standard view that modern science arose in the 15th and 16th centuries, primarily as a recovery of Greek science. But the better empirical technology of the new science was the product of the medieval centuries; and its method of exposition was a contribution of scholastic thought.

Astronomy—which cannot at this stage be distinguished from astrology—was certainly the main scientific interest of the scholastic age, but its practical results are meagre. Western knowledge of astronomy was largely based on the activity of King Alfonso X the Wise of Castile, who collected at Toledo a body of scholars, mostly Jews, who had access to Arabic sources and calculated a set of astronomical tables (1252; *see* ALPHONSINE TABLES).

In pure mathematics the original achievement of the scholastic age was small, though a borrowed element, the so-called "Arabic" notation, was the source of the modern method of notation, which, however, was adopted only very slowly. The *Liber abaci* of Leonardo of Pisa (*c.* 1170–1230), which advocates this system with great skill, appeared in 1202, and is the first book by a Latin Christian to employ it. Other works of Leonardo were much more original, but being before their time had less influence.

VII. THE RENAISSANCE AND EARLY MODERN SCIENCE

1. The Humanistic Century (1450–1550).—The Western recovery of the Greek classics from surviving Greek traditions and texts was in full action by 1450, and the scientific heritage had been completely recovered by 1550. This century saw also the introduction and spread of printing and illustration.

The first Latin exponent of the value of experiment is the German cardinal Nicholas of Cusa (1401–64), whose recorded careful experiment on a growing plant, proving that it absorbs some weight from the air, is the first modern formal biological experiment and the first experimental proof that air has weight. Carried to its logical conclusion it would have ended the old doctrine of the pneuma. Nicholas wrote a book on the use of the balance and showed that he could apply the experimental method in detail. His views led him to believe that the earth moves, though he reached no formal astronomic theory.

Copernicus (1473–1543), despite the vastness of the scientific change involved in his theory of the earth's revolution around the sun (*see* ASTRONOMY: *History of Astronomy;* COPERNICUS, NICOLAUS), was a scholar more than an observer, and conservative. Although he was aware of error in the Ptolemaic system and although he knew that some Greek philosophers (including, it is believed, Aristarchus) had held that the earth moved, his heliocentric theory retained the Ptolemaic ideas of the sphericity of the universe and its limitation by the sphere of the fixed stars. He retained also the conception of uniform circular motions of the celestial bodies, as well as some of the Ptolemaic epicycles (the

smaller of the circles in which the sun and planets moved).

Important during the humanistic century is the impact of the main technical instrument of Renaissance art, namely perspective. This new device, though it rapidly became a convention, is truly scientific because, given certain conditions, its truth can be demonstrated experimentally and its accuracy estimated. Leonardo da Vinci (1452–1519) was its greatest scientific exponent, but it was the product of many minds. It produced sounder and simpler plans of engines of all kinds and was of great aid in many technical arts. All developments involving geometry in three dimensions became more easily intelligible. Above all it made possible the adequate representations of living things and their parts. Thus Leonardo could both illustrate many devices and make clear on paper, for the first time, many details of the structure of human and animal bodies.

This same movement produced in the first half of the 16th century many exact studies of plant form. Its most characteristic product was the *De humani corporis fabrica* (1543) of Andreas Vesalius (1514–64), the first great scientific monograph in the modern manner, which appeared within a few weeks of the work of Copernicus. Copernicus is essentially a medieval figure, Vesalius a modern who employed all the resources of the art of his age to illustrate personal observations. But it must be remembered that the researches of Vesalius were solidly and consciously based on knowledge of the 1,300-year-old findings of Galen.

2. The New Status of Greek Science.—Medieval thought on the material world was essentially based on that of the Greeks and especially on Aristotle. By 1500 the whole works of Plato and almost the whole of Aristotle were available in reliable Latin translations direct from Greek. The Renaissance saw a revival of Platonic thought. Moreover, from about 1550 an accumulation of biological works based on Aristotle tended to confirm him as "the master of those that know" in that field. At about the same time, however, in the fields of mechanics and of cosmology, cracks were beginning to appear in Aristotle's system. These were brought out clearly by Simon Stevin (1548–1620) in the last years of the 16th century. He investigated the Aristotelian theory of the fall of bodies. His name is associated with the method of resolution of forces, with the distinction of stable and unstable equilibrium, and, above all, with the law of equilibrium on an inclined plane in a famous demonstration of the impossibility of perpetual motion. He perceived that science could not well advance until its mathematical framework had been improved. This was facilitated by his introduction of decimal fractions. Several other contemporary devices helped in the same direction: for example, the employment of letters to represent quantities (1591), the conception of conic sections as stages in a series from the line pair to the circle (1604), and the invention of logarithms (1614). With such equipment and with the improvement in the technique of instrument making, notably of lenses, the great exponents of scientific method of the earlier part of the 17th century —Galileo (1564–1642), Kepler (1571–1630), Descartes (1596–1650)—could proceed with their work. By the middle of that century Aristotle's physics and cosmology had fallen, while his biology was on its way to being rebuilt on his own lines; mathematics had become a recognized instrument of research in the physical sciences; the contributions of Archimedes were recognized, even when applied in the biological field; alchemy had effectively been replaced by a chemistry built mainly on the technological traditions of craftsmen but aided by the apparatus of the alchemists; the exploration of the structure and function of the human body had become a profession. Science itself had emerged as a vocation supported by its specialized philosophers, by its specialized exponents in the arts of discovery in various departments, and by its skilled instrument makers. Science had thus become consciously mature and was prepared for its formal organization in the period which followed. All this was exemplified in the brilliant personality of Galileo.

3. The Beginning of the Modern Scientific Outlook.—The outlook of the first half of the 17th century thus involved on the negative side a rapid waning of the scholastic reliance on ratiocination, and on the positive a new reliance on experience and especially on experiment as a way to acquire knowledge. A man of science of the 20th century could converse freely with one of 1650, with a very few of 1600, with a handful of 1550, but hardly with one of 1500. What had happened in this first and critical half-century of modern science, from 1600 to 1650?

In cosmology, the explanation of planetary movements by Kepler and Galileo's discoveries with the telescope had destroyed geocentric thinking. They had done away with the moral connotation of physical events expressed in the idea of the perfection of the sphere. Incidentally they had destroyed astrology.

There was a new view of the nature of matter. The systematization of mineralogical knowledge and the increased literacy of industrial technicians had given birth to chemistry and destroyed alchemy, removing there too a moral significance from material phenomena.

To express his findings in mathematical terms became the ideal of the physical experimenter. Broadly, this was acceptance of a relation between number and form, for which Descartes is still commemorated in the term "Cartesian co-ordinates."

The idea of acceleration is a development of that of mathematical expression but one of such significance that it demands special mention. Its introduction by Galileo was a great seminal idea for all aspects of physics and notably for celestial physics.

Physiology set physics as its ideal. The discovery of the circulation of the blood by William Harvey (1578–1657) and the chemical investigation of the bodily processes by J. B. van Helmont (1577–1644) made possible the first comprehensive treatment of the subject by Descartes.

Aristotelian methods were extended to the classification of animals and of plants. "Natural history" perhaps first achieved this status at the hands of Joachim Jung (1587–1657).

From this point on it is harder to consider science as a whole. Specialization began. Having dichotomized into mathematics and medicine at its dawn about 400 B.C., science had now developed physico-chemical and biological branches. Soon there would be much more complex division and recombination.

VIII. DETERMINISM AND POSTDETERMINISM

From the second half of the 17th century to the end of the 19th men lived in a world of which the material framework had been outlined by Isaac Newton (1642–1727). The attitude of mind called "scientific determinism," sometimes rashly equated with "scientific materialism," is not quite as old as that. Newton's great work, *Philosophiae Naturalis Principia Mathematica*, was published in 1687. It had little immediate effect: it could at first be read only with difficulty even by mathematicians, and its demonstrations were intelligible to a mere handful of Newton's contemporaries, none of whom, moreover, was interested in introducing them to less scientific readers. Its wider influence began to be felt after Newton's death.

Newton left no doubt as to what he regarded as the principles of science and his hopes for it. All its difficulties, he held, "seem to consist in this—from the phenomena of motions to investigate the forces of nature, and then, from our knowledge of these, to demonstrate other phenomena." And he goes on: "I wish I could derive all phenomena of nature by some kind of reasoning from mechanical principles; for I have many reasons to suspect that they all depend upon certain forces by which the particles of bodies are either mutually attracted and cohere in regular figures or are repelled and recede from each other." Thus he hoped to fit all material events into a framework of relatively simple and mathematically expressible rules. That is what he regarded as the task of his "philosophy" and what for two centuries was regarded as the task of "science."

Newton's marvelous genius ran at its ease only along the line of demonstration to the senses, and it was as a means for such demonstration that his superb mathematical apparatus was designed. He was also much interested in theology and spent much time on it; but for philosophy (in the modern sense) he had a definite distaste. The influence of his science on philosophy (and doubtless through it on religion) has mostly been unwitting, though no less important on that account. But this scientific giant pre-

sents a different figure when he works in a field ill-suited to his trained talents, and with tools the use of which he had not learned in the best tradition: Newton's incursions into chemistry, which consisted of experiments on alchemy, make a depressing story of waste of most precious effort.

In spite of all this, Newton formulated, more clearly than any of his predecessors, those primary statements on which "scientific determinism" came to be based. The term was introduced about the middle of the 19th century, but the passages just quoted from Newton's *Principia* contain the essential elements in the determinist faith. Some of its exponents have, however, extended the conception of "phenomena" to include events within the mind itself, treating them also as determinate.

The conception that mental events are determinate has been much more revolutionary for religion than anything in the Newtonian system proper. That man's body works on ascertainable mechanical principles had indeed seemed obvious to Descartes before Newton and as long ago as 1627. The followers of Descartes directed the thought of the age for about a century. The Cartesians, however, recognized with their master that men are more than mechanical systems. Only if man's entire nature, including his thinking, could be fitted into a long chain of causal development could his actions and his mind be treated as truly determinate. It was in this very direction that the conceptions of Descartes and Newton were extended in the middle and later years of the 19th century, especially after 1859, in which year appeared both Darwin's *Origin of Species* and Marx's *Zur Kritik der politischen Ökonomie*. The former contains the germ of biological determinism, the latter that of psychological determinism. Both are sources of the doctrine of social determinism.

Admittedly in the 18th century the French encyclopaedists and some of the first English utilitarians had been determinist; as, in some sense, had been certain Renaissance and medieval heretics; and a number of thinkers of antiquity. But it was Newton who first demonstrated a law of physical movement which seemed wholly unrelated to any spiritual order. It was this that gave to the conception of determinance an immediacy as well as a practical workaday aspect that it had never previously worn.

Although Newton, like many thinkers, sought always to cast his scientific conclusions into a mathematical form, in fact much science is not, or has not yet become, mathematical.

So far as the 19th century is concerned, it was the geologists and the evolutionary biologists who raised most acutely the issues primarily responsible for "the conflict between religion and science," by demonstrating that man's place in nature is very different from that which had been taught. Evolutionary doctrine quickly affected historical, social, linguistic, and even literary studies. No line of scientific thought has so rapidly seized so many minds as that associated with Charles Darwin (1809–82). Now, however, the thunders of the evolutionary conflict rumble only from the further frontiers of philosophical discussion.

But in considering this and other great seminal ideas it must always be borne in mind that science never considers and cannot consider the world as a whole. It is essential to any science that it proceed by abstracting a part of the universe, to be considered by and for itself. This fragmentation carries with it the secret of the scientific triumph and the secret of a common philosophic fallacy. While one science may combine with another to form a new science with its own technique (for example, entomology and psychology have together produced insect psychology), and while one science can use the results of another, yet each science can describe only its own little bit of the universe in its own terms. These terms are derived by a comparison of yet smaller bits of the universe with other smaller bits. Such terms have little or no application outside the science for which they were devised.

Gross errors have been made, even by scientific men, through transference of scientific terms from their original field of reference. This may be seen from, for example, the mass of fruitless disputation that has arisen around such words as "evolution," "instinct," "element"; or the employment of the words "race," "tradition," "heredity," "nationality," "value" to give a scientific appearance to nonscientific judgments; or, again, the endless confusion between the scientific, the philosophic, and the theological usages of such terms as "substance," "theory," "idea," "cause," "purpose," "function." The language of the sciences is peculiarly difficult to master, for language is a product of complex and ever-changing social conditions.

The definition of terms cannot be discussed in this article; it must suffice to indicate that there cannot be a "science" of the whole universe: for it is impossible to attain this by adding the sciences together, and there are vast regions of experience, such as art, literature, and philosophy, that are refractory to scientific treatment. In any event, there is no such thing as a unitary scientific treatment of the material universe.

Nevertheless, a science must not be mistaken for a mere fragmentation of knowledge, despite the necessary minuteness of scientific analysis, which may give to the untrained an impression of triviality. The objective of scientific analysis is to reach a series of points—a natural frontier—from which the mind can return along its tracks to arrange its findings into a theory or generalization. This frequently involves a reunion of the findings of workers in different departments. Often these findings become the starting places for new analytic explorations and the bases of yet further generalizations and thus of new sciences.

The great scientific generalizations are, however, essentially abstractive; and by verbal though not real paradox, the astronomer's "expanding universe" is as much an artificially separated fragment of the universe as the minutest entomological research. The "expanding universe" of the relativists is, after all, not the universe of ordinary thought, but simply a technical term referring to something the existence and growing size of which must be assumed in order to fit together the mathematical deductions from certain physical measurements.

During the 20th century it became increasingly apparent that a necessary condition for scientific observation is the postulation of certain basic data, things "given" or taken for granted (*i.e.*, metaphysical foundations); as is shown in the famous saying of Archimedes: "*Give* me a place on which to stand, and I can move the world." This necessity is strikingly illustrated by Einstein's theory of relativity, the essence of which may be expressed by saying that the very act of observation affects that (*i.e.*, the behaviour of light from the stars) which is to be observed. Similarly, in connection with intra-atomic physics, it was found that the more accurately the position of a particle could be specified, the less accurately could its velocity be predicted, and vice versa. The principles of "indeterminancy" or "uncertainty" (*see* UNCERTAINTY PRINCIPLE) and of relativity run athwart the whole view of scientific determinism and are of great importance for the consideration of the ultimate validity of scientific demonstration. It cannot, however, be assumed that, because minutely exact prediction may be impossible, physical action is ultimately indeterminate. The element of indeterminancy may be in the researcher rather than in nature; and in any case whether it is or is not possible to ascertain all the determinate elements in nature is an entirely different question. Moreover, as neither physical relativity nor physical indeterminancy is involved in the individual observational sciences, a scientific theory can generally be safely launched regardless of them. It should, however, be remembered that scientific conclusions are essentially partial or temporary; that even the great generalizations are not goals but starting points for further exploration; and that the sciences can at best describe only a part of the universe.

To the question "What does science say about religion?" the strictly true answer is "Nothing"; if by religion is meant the view that the universe has a meaning, an idea of what its meaning is, and an idea of man's place in it. Admittedly, science can analyze the effects of a particular religious system on the outward conduct of a society or of an individual; but it cannot pass judgment upon its validity nor touch the essential nature of existence, of which man is aware through "consciousness."

Consciousness is the ultimate datum, the thing taken for granted; the judge, as it were, before whom science must recite its narrative of experiences of phenomena. Their recital, and that alone, is the role of science.

SCIENCE, TEACHING OF. In most countries, science instruction begins in the elementary school. The teacher at this level cannot be a specialist in science teaching, for he must also teach the other subjects of the curriculum, but there is a growing tendency to employ specially trained science consultants who do demonstration teaching in science and who assist the regular teachers in their work.

The teaching of science as a separate subject generally begins with the middle or junior high school (typically, grades six to eight or seven to nine; *i.e.*, second to fourth or third to fifth form). Instruction at this level in Great Britain, the United States and many other countries offers, under the heading of general science, all major aspects of the subject. Many countries, however, follow the French system of offering separate courses in physics, chemistry and biology, starting with simple and descriptive accounts in the sixth or seventh grade (second or third form). The instruction in these fields is typically cyclical, and the instruction continues throughout the secondary school. The Anglo-U.S. pattern of general science is followed by courses in physics, chemistry and biology in the later secondary-school years. Less rigorous courses such as physical science are sometimes offered for less capable students.

Postsecondary-school science courses are many and diverse. Universities offer sequences in each major field of science, from introductory and general courses to highly specialized courses which provide intensive instruction in restricted fields leading to research or to technical vocations. Technical schools provide specialized training for industrial work; science instruction in such schools is focused more on the practical than on the theoretical aspects of science.

Goals of Science Teaching.—The modern world requires a very large number of skilled technicians and practitioners as well as of persons who can add to the store of fundamental knowledge through their own research. A primary responsibility of the science teacher, therefore, is to foster the development of the scientist. But there is a second goal, no less important, which is that of educating each person, to the degree of his capabilities, in scientific understanding to enable him to cope intelligently with his environment and to contribute both to his own well-being and to that of society. Another way of looking at goals is to examine the nature of science itself. Science is, first, a body of tested facts and concepts that satisfactorily interpret natural phenomena and disclose causal relationships, and, second, a means for discovering such facts and principles and for applying them in the solution of problems. There is no single "scientific method," but there are general procedures which distinguish the scientific methodology as a discipline from the methodologies of other fields such as art or philosophy. This aspect of science, heavily emphasized in graduate programs of universities, formerly had little attention at lower levels, particularly in European schools, but emphasis on scientific attitudes and methods as an instructional goal is increasing.

Methods of Science Teaching.—Methods are a reflection of goals. For example, the development of knowledge sufficient to pass the rigorous governmental examinations has been a chief instructional goal in the French *lycées*. As these examinations emphasize detailed memory of facts and principles (and, at least formerly, largely ignored reflective analysis of data, applications of principles, and so forth), instruction has placed a premium on memorization. The formal lecture method is widely employed, and students are expected to take notes and to remember what the teacher has taught. Laboratory work is seldom used, and even demonstrations are generally neglected in favour of a systematic and highly verbal treatment of a logically organized body of scientific facts. Practice in the U.S., as another example, has tended in the opposite direction. The secondary schools have placed a much stronger emphasis on individual laboratory work, demonstrations, problem solving and informal lecturing and discussion. About the middle of the 20th century, however, an American trend toward greater rigour and systematic instruction was paralleled by a European trend toward greater flexibility with less emphasis on strictly memory work. (R. W. Bu.)

SCIENCE FICTION deals with the human drama, the conflicts and adventures, arising out of scientific discovery in the future. There are two basic types. Science fiction proper, an almost step-by-step development of possibilities from known scientific or social data, is exemplified by Arthur C. Clarke's *The Sands of Mars* (1952), which works out the conditions encountered by the first explorers on that planet; by Hal Clement's *Mission of Gravity* (1954), which deals similarly with an entirely alien world and its beings in another solar system; and by George Orwell's *1984* (1949), which presents an uncannily perceptive extrapolation from contemporary totalitarian social patterns. Science fantasy, on the other hand, can leap directly to whatever farfetched assumptions may be necessary to the story. Obeying the sole requirement of dramatic plausibility, it permits the imagination not only to go beyond the known and proved but to contradict it when that is necessary, as exemplified by Alfred Bester's *The Demolished Man* (1953), Ray Bradbury's *The Martian Chronicles* (1950) and Edward E. Smith's *Lensman* series (various dates). Needless to say, the two basic types are frequently combined.

The major themes of science fiction are: (1) space travel to and from other planets, solar systems and galaxies, including the exploration, settlement and exploitation of other worlds as well as encounters with, or between, extraterrestrial life forms; (2) time travel to the future or the past and, similarly, travel to "alternate universes" which are usually different versions of our own; (3) psychological and biological changes in man, brought about by nature or science, and similar changes in other species; (4) "supernormal" powers and talents, achieved either through technology or the advancement of such "fringe sciences" as parapsychology; (5) science applied, directly or indirectly, to human relations for either constructive or destructive purposes. These themes are clearly illustrated in such short-story anthologies as Groff Conklin, *The Best of Science Fiction* (1946) and *A Treasury of Science Fiction* (1948); August Derleth, *Beyond Time & Space* (1950); and Raymond J. Healy and J. Francis MacComas, *Famous Science Fiction Stories, Adventures in Time and Space* (1957).

History.—Even in ancient times certain science-fiction themes were used as vehicles for social satire and criticism and for tales of wonder. These treatments dealt with what was then admittedly impossible. True science fiction, however, assumes a "this *can* happen" attitude which could not exist until the scientific method was defined and until the mechanization of everyday life made great numbers of people aware of science. It was not until the latter part of the 19th century, especially in the works of such writers as Jules Verne and H. G. Wells (*qq.v.*), that science fiction began to acquire its 20th-century forms and its functions not only of entertainment but of speculation and prophecy. In this last it has been more accurate technologically than socially.

As a separate and self-aware literary form, science fiction may be said to date in the United States from Hugo Gernsback's founding in 1928 of the magazine *Amazing Stories*. In 1937 it entered a new epoch when John W. Campbell, Jr., took over the editorship of *Astounding Science Fiction* and established a story pattern emphasizing not only the element of scientific speculation but those of character and human drama as well. Advances in

nuclear power and rocketry during and after World War II increased its popularity tremendously. In the United States the number of specialized magazines rose from 8 in 1945 to more than 30 a few years later, and the number of novels and anthologies increased even more rapidly. Serious journals of comment and opinion took note of science fiction. The general magazines, motion pictures, radio and television began to use it much more often. A specialized critical literature came into being.

This phenomenon was especially marked in the United States and the rest of the English-speaking world; however, in varying degrees it took place in most civilized nations—for science fiction had accomplished something unique in the history of literature. The central technological achievements of the period—radar, television, automation, electronic brains, atomic power for peace and war, rockets and earth satellites—had been science-fiction commonplaces for a generation before their practical realization. With a remarkable degree of general accuracy science fiction had heralded and defined the electronic age, the atomic age and the age of space.

Influence.—Through its readers science fiction had considerable sociological influence. Surveys showed that many of the readers of the better science-fiction magazines were young scientists and technologists or students destined for these fields. Similarly, many science-fiction writers, such as Arthur C. Clarke, Isaac Asimov, Robert Heinlein, John Taine and Edward E. Smith, were themselves scientists or engineers. Science fiction influenced many young people to choose the sciences as a career; it stimulated the imaginations of many scientists in the forefront of discovery; it helped to orient many intelligent laymen to the scientific world of the present and the future.

Nevertheless, science fiction did not break with literary tradition. The same artistic rules apply to it. Its characters must be as fully developed as any others; its plot structures must be as coherent; its emotional impacts must be just as strong. That is why, with the infinite variation of its themes, it holds at its best so much for readers and writers alike.

SCIENTIFIC MANAGEMENT: *see* MANAGEMENT SCIENCES.

SCIENTIFIC METHOD is a description now reserved for the procedure by which we gain knowledge in empirical studies such as physics, chemistry, and physiology. At one time the word "science" was applied to all systematic studies or organized bodies of knowledge, including mathematics and theology. There was a tradition derived from Plato and Aristotle that the system to be expected in a science should be such as we have in mathematics; that is, that all the asserted propositions which are not themselves self-evident should be derived from others that are self-evident. In accordance with this usage the word "scientific," first introduced in its Latin form as a rendering of *epistemonikos* in Aristotle's *Posterior Analytics*, i, 2, was applied only to reasoning which produced knowledge like that which we have in mathematics. For many centuries it remained a synonym for "demonstrative." Thus John Locke says in his *Essay Concerning Human Understanding*, iv, 3, § 26, "How far soever human industry may advance useful and experimental philosophy in physical things, *scientifical* will still be out of our reach"; and he explains his meaning later in the paragraph by the remark "*Certainty* and *demonstration* are things we must not in these matters pretend to."

The modern use of "scientific" noticed above appears to have been established in England about the middle of the 19th century. At the beginning of that century physicists and chemists were still called philosophers, and the tools of their trade philosophical instruments. The word "scientist" was invented by William Whewell in 1840, and the earliest evidence in the *Oxford English Dictionary* for an acknowledged particularization of the word "science" in its special modern sense comes from 1867.

Clearly there may be many different methods by which scientists gain knowledge in different fields of research. Thus Archimedes found a way of determining specific gravities, and A. H. L. Fizeau found a way of measuring the speed of light. In modern times the special methods of research used in the various sciences have become more numerous and more complicated, so that a large part of the training of a future scientist is the imparting of techniques. Knowledge of these is important not only because it is necessary for one who is to make new contributions as an experimenter but also because it is an indispensable link between observation and theory.

A physiologist may use a cathode ray oscillograph without being an expert in electronics, but it will not help him to get evidence for or against a hypothesis about the working of nerves unless he understands its own working at least in outline. Since such a special method involves application of scientific results already attained, it cannot be expounded without an exposition of science. But when we speak of scientific method in the singular, we ordinarily mean some pattern of reasoning common to all empirical sciences, and that is the subject of this article.

Traditional Views: From Aristotle to J. S. Mill.—If there is any common method of the sciences it must obviously be related to what is common in the aims of the various kinds of scientists. Aristotle gives two accounts of the matter which had great influence on subsequent thought.

In the first place Aristotle introduces the notion of induction (*q.v.*) as a way of learning distinct from demonstration and logically prior because it provides the premisses needed for demonstration. But in his *Prior Analytics*, ii, 23, he talks of induction as a kind of syllogism in which we reach a universal conclusion from an exhaustive survey of the cases it covers; and in his *Posterior Analytics*, i, 1 and 18, he talks of induction as the establishment of a universal truth by consideration of an instance or instances which reveal to thought the necessity of the connection asserted. In modern times these two distinct procedures have been called summative and intuitive induction respectively. Neither can be identified with the procedure of ampliative induction, by which universal propositions are in fact established in the empirical sciences. For scientists do not claim to have proved that copper is a good conductor of electricity by examining every specimen of copper, nor do they claim to have discovered the necessity of the connection by careful reflection on some single experiment. Secondly, Aristotle says in various places (*e.g.*, in *Posterior Analytics*, i, 2) that science is knowledge of causes (*see* CAUSALITY). Perhaps he meant by causes in this context much the same as we mean by "explanations," but his detailed account of the various kinds of causes that he recognized would not be accepted by modern scientists as a statement of their objectives, and the doctrine is not in any case connected with either of the accounts of induction noticed above.

For more than 2,000 years, however, these two pronouncements of Aristotle determined the course of discussion about scientific method even among those philosophers who professed hostility to his doctrines. Thus Francis Bacon, David Hume and J. S. Mill (*qq.v.*) all assumed that the business of the empirical scientist was to establish universal propositions about causal connection, though they differed from Aristotle in the accounts that they gave of causes. Some part of scientific activity may indeed be described as a search for causes of kinds of phenomena, but it now seems clear that this is not a satisfactory description of all that scientists try to do. We need consider here only the general outline of the doctrine which was introduced by Francis Bacon in his *Novum Organum* of 1620 and accepted for a long time after as a correct account of the method of the new science.

According to Bacon it is the business of the scientist to discover the "forms" of phenomena, but in his usage this word "form" (derived presumably from Aristotle's theory of formal causes) means what would now be called a necessary and sufficient condition.

Thus F is the form of P if and only if P never occurs without F but always occurs with F. If either is capable of varying in degree, it is required also that the other should vary in similar fashion. For the discovery of forms in this sense the proper procedure is to digest our information about the phenomenon in three tables showing presence, absence and degrees: the first includes positive instances of the phenomenon, the second negative instances (*i.e.*, cases which are in most respects like known positive instances but do not in fact exemplify the phenomenon under investigation) and the third instances which vary in degree. Together they should enable us to refute all false suggestions put forward in reply to the question "What is the form?" and so to reach the true answer by elimination. We can say, for example, that anything which does not vary in degree when the phenomenon under investigation varies cannot be its form. It is assumed, of course, that every phenomenon must have a form, or necessary and sufficient condition.

J. S. Mill, whose *System of Logic* (1843) had great influence in the 19th century, wrote of causes rather than forms, but defined a cause as an invariable antecedent and modeled his account of induction on Bacon's. He spoke of it, however, as employing a number of different methods: for example, a method of agreement, in which the cause of a phenomenon is revealed by the consideration that it is the only circumstance (other than the phenomenon itself) in which positive instances agree; and a method of difference, in which the cause is revealed by the consideration that it is the only circumstance (other than the phenomenon itself) in which a positive and a negative instance differ.

This doctrine of scientific method could not have obtained the popularity that it once enjoyed if it corresponded to nothing at all in scientific inquiry. Mill's method of agreement is indeed used in the purely observational sciences and his method of difference in the experimental sciences. But the doctrine does not cover the whole field of scientific activity and moreover is misleading in its suggestion that the business of discovery can be reduced to rules. Even when the work of a scientist can be described without distortion as a search for necessary and sufficient conditions, it is not correct to assume that he can find these by application of a standard procedure.

Bacon and Mill both take for granted that there is no serious difficulty in drawing up an exhaustive list of circumstances which deserve consideration in a search for the necessary and sufficient condition of a phenomenon; yet there is in fact nothing to indicate what should be considered in this connection as a single circumstance. When we single out for attention half-a-dozen distinct features of events, say A, B, C, D, E, and F, why should we not also take account of their conjunctions and disjunctions, that is to say, of complex features such as might be represented by "A and B," "C or D" or even more complicated formulas like "[A or (B and C)] and [(D and E) or F]"? And if we allow for all this complication what assurance can there be that the half-dozen features with which we started are the only elementary features that deserve consideration? Mill admits in a somewhat half-hearted way that there may be what he calls plurality of causes, but he does not recognize that his methods are defective in general for lack of any systematic enumeration of possibilities.

Varieties of Scientific Activity.—It is very difficult indeed and perhaps not very profitable to find a formula which will adequately characterize all scientific activity. For while some scientists are concerned for all or most of their time with the making of generalizations from experience, others are concerned more with the elaboration of deductive systems in which such generalizations may be derived from hypotheses that cannot themselves be tested directly because they deal with unobservable entities such as electromagnetic waves. And apart from these two groups, whose methods may be called primary and secondary induction respectively, there are others whose interest in nature is more like that of a historian. Thus the palaeontologist who tries to trace the biological evolution of man wants to discover what happened in certain places at certain times, and the geologist and the cosmologist are equally interested in the course of past events. All use generalizations, but none of them is primarily interested in these for their own sake. If such inquiries are to be called scientific, it is not even correct to say that all empirical science is inductive, unless indeed the meaning of the word "inductive" is stretched to cover not only the secondary induction noticed above but also any reasoning concerned in any way with generalizations from experience. Perhaps the best we can say is that the pursuit of science is the search for knowledge and understanding through formulation of the laws of nature. This excludes the collection of disconnected scraps of information and draws attention to the special importance of natural laws in our conception of science. Whatever can be said usefully about scientific method in general must be related to these.

The beginning of science is classification (*q.v.*). Whatever we recognize must be of some kind, and language even at its lowest level is full of general words. But the same things may be classified in many different ways; *e.g.*, according to size, to shape, or to colour. Each classification is based on real characters of the things classified, and each may be useful for some human purpose. There are, however, some that seem more important than others, those, namely, for which the classifying terms of our most primitive language are nouns as distinct from adjectives. Thus "grass," "tree," "stone," "cow," "horse" and "dog" are said sometimes to mark natural kinds, whereas "red," "square" and "hard" serve only for artificial grouping. The point of the distinction is not that we can make anything red or square or hard by calling it so but rather that recognition of a thing as a piece of grass or as a tree or as a stone is the gaining of an important clue to what may be expected of it. If the thing before us is a blade of grass, then it will probably grow bigger, but not to a height of more than a few feet; when touched, it will bend; after a few months it will turn brown and gradually decay; and so on. It is not necessary, however, that I should satisfy myself of the thing's behaviour in all these respects before venturing to call it grass: fortunately I can recognize grass by its appearance and then make a number of prophecies about it with fair confidence. There is very little, on the other hand, that I can safely assume about the future behaviour of a thing merely because it is red.

Here, then, in the classifications called natural, we have the beginning of our intellectual mapping of nature. Long before there was any conscious pursuit of science men took it for granted that there were bounds to natural possibility; *i.e.*, that not all the conceivable combinations of characters were realized in nature. We cannot discard all their assumptions without abandoning also the language inherited from them; but we can and do improve on their classifications. Many of the terms for metals, which our children learn with ease because of the importance of metals in modern life, have been added to the vocabulary of men within historic times.

Primary induction is the deliberate attempt to find more laws about the behaviour of the things that we can observe and so to draw the bounds of natural possibility more narrowly. In so far as it is successful, it enables us to make more inferences from the observed to the unobserved and, in particular, more predictions by which we may guide our conduct. But this is not its only value. Already at this stage there is intellectual satisfaction to be had in the discovery of laws: we have a beginning of explanation when we can say that a piece of wire has melted in a candle flame because it is lead and lead always melts at the heat of a candle flame.

Sometimes scientists or writers on science who are interested chiefly in the more advanced stages of science speak of primary induction as though it scarcely deserved to be called scientific. And it would indeed be a great mistake to suppose that science is never anything more than the making of generalizations in the fashion of 17th-century naturalists. But generalization from experience is an indispensable feature of science. In the more advanced sciences such as physics and chemistry, observations are directed by an interest in theory (*q.v.*); but what the scientist deduces from his theory and then tries to test by observation or, if possible, by experiment (*i.e.*, observation in circumstances over which he has control) is always some universal proposition. Here primary induction comes late in the temporal order of a scientist's activities, but it is still primary in the sense that it is basic in his final argument and logically independent of the superstructure of theory. For a generalization which has been confirmed by experi-

ence only after it has been deduced from a theory is not invalidated by the discovery of a flaw in the theory, though it may perhaps lose something in reliability when it is no longer linked with other generalizations through the theory.

With primary induction we may conveniently include arguments of the kind sometimes called proportional generalizations. If we have observed many *A* things and found that the frequency of *B* things among them has remained fairly constant in the neighbourhood of a fraction *f*, we are inclined to say in general terms that the proportion of *A* things which are *B* is about *f*. Unless the class of *A* things is known to be finite, we cannot take this remark as an ordinary statement of proportion; but in practice we may use it as a guide to expectation, when we wish to know whether something which is *A* is likely to be also *B*. Often it is said to be a statement of the probability (*q.v.*) of an *A* thing's being *B*.

Secondary induction is the attempt to incorporate the results of primary induction in an explanatory theory covering a large field of inquiry. At this level in science it may be impossible to make progress without the introduction of concepts far removed from those used by primitive men in their classification of perceptible objects. In retrospect we can see that physical theory has contained such concepts for a long time (*e.g.*, the concept of energy); but until the 20th century the fact could be ignored because it was still possible to provide in imagination some sort of model for the interpretation of the statements of physical theory. When it was supposed that electromagnetic waves were transmitted through an ethereal jelly, the model was already inappropriate in some features but not in so obvious a way that it could not still be taken seriously by great scientists. Since then the difficulty of bridging the gap between theory and common sense has become more obvious. Modern views on this subject are discussed in EXPLANATION.

The Role of Hypothesis.—From the nature of the scientific enterprise it is clear that the reasoning by which it proceeds cannot be reduced to validating schemata like those of deduction; that is, to patterns of inference which guarantee the truth of the conclusion provided only that the premisses are true. There may of course be deductive arguments in natural science, but the laws and theories which are said to be established by scientific research are not deduced from observations. On the contrary, each is put forward first as a hypothesis (*q.v.*) which together with certain initial data entails the facts of observation. Our effort is to construct a deductive system "from the wrong end up" but not a trivial system in which the hypothesis itself could be deduced from the facts of observation. To be worth consideration a hypothesis of law must restrict the field of possibility more than that field is already known or assumed to be restricted; and similarly a suggested theory must be more restrictive than the set of laws which it is supposed to coordinate and explain; in other words, it must have some consequences other than those we already accept.

For these reasons it has been said that the conclusions of ampliative induction are never more than probable; but this pronouncement is unfortunate in some ways. The word "probable" is ordinarily used to recommend propositions when we are not completely satisfied about them; but we do in fact claim to know some results of induction (for example, that arsenic is poisonous), and adoption of the suggestion that we should apply the word "probable" to all results of induction would therefore lead to a blurring of a useful distinction. On the other hand, it is important to appreciate that the cases in which we say that we know some result of induction differ only in degree from cases in which we are not prepared to commit ourselves by use of the word "know"; and this is at least part of what philosophers have tried to convey by saying somewhat paradoxically that the results of induction are never more than probable. In mathematics, a general proposition such as C. Goldbach's conjecture of 1742 that every positive even integer is the sum of two primes (*see* NUMBERS, THEORY OF) may perhaps be regarded as highly probable because it has so far survived all attempts to find a counter-example. But no accumulation of evidence of this kind would ever justify a claim to knowledge of the truth of the generalization: for that, it would be necessary to produce an argument of a totally different kind, and the possibility of such an argument is at least conceivable. In natural science, however, there can be nothing corresponding to mathematical proof, and the customary requirement for the use of the word "knowledge" is therefore different.

The theory of statistics (*q.v.*) supplies principles for the marshaling of complex evidence in many different inductive studies, but if we take "scientific method" to mean a rule or set of rules by obedience to which any fairly intelligent person can make discoveries in natural science whenever he wishes, we must admit that there is no scientific method. For the all-important act in scientific discovery is the finding of a hypothesis that will survive testing, and this cannot be reduced to a routine. When we are looking for a necessary and sufficient condition of a phenomenon, or, less exactingly, for a sufficient condition only, we naturally consider only circumstances which are to be found accompanying some instance; and attempts were made by Bacon and by Mill to formulate rules of primary induction on this basis.

But the notion of accompanying is not very precise, and it is in fact impossible to set out any exhaustive list of circumstances that deserve consideration, because an intellectual search of this kind admits of no device like the systematic quartering of the ground by which we can make sure of success in a search for some material object that has been lost. An argument from analogy (*q.v.*) may perhaps suggest an interesting hypothesis here or in secondary induction, but again there is no infallible procedure for discovering fruitful analogies. The finding of the right hypothesis is always a problem, rather than a task. But in this it resembles the finding of proofs in most parts of mathematics, and it must not be thought that success in either case is just a matter of luck.

If we take "scientific method" in the looser sense of a program or policy, then undoubtedly there is a scientific method, namely the policy of making hypotheses for the purposes of primary and secondary induction as described above. Once formulated, this seems to be obviously rational, and some philosophers of modern times are inclined to talk of such scientific activity as though it were nothing but the commonest of common sense. But the deliberate pursuit of knowledge by this method is a comparatively recent enterprise of mankind: at the beginning of the 17th century, when Bacon wrote his *Novum Organum,* it was a novelty not very well understood; and a thinker as great as Descartes could maintain that there was no essential difference between physics and geometry. A hundred years later, after the founding of the Royal Society and the great triumphs of Sir Isaac Newton, the method was still something that could arouse debate among intelligent men, as may be seen from the curious remarks of Newton in the *General Scholium* that he added at the end of his *Principia.* In 1739 Hume, who thought Newton "the greatest and rarest genius that ever rose for the ornament and instruction of the species," found himself driven nevertheless to the conclusion that induction could be nothing but customary association of ideas (which Locke had called "a sort of madness") because it was clearly not to be justified as a form of deduction. If the method or policy now seems obviously wise, that is because we understand our situation better than our predecessors did and are therefore no longer inclined to think we can get what we want in any other way.

Presuppositions and Aims.—It has sometimes been suggested that scientific method involves use of a postulate called the Principle of the Uniformity of Nature. According to those who proclaim it, this principle is needed as a supplementary premiss by addition of which inductions can be converted into valid deductions. But no one has ever succeeded in formulating the proposed principle in any way which makes it seem at all plausible, and we have seen reason to believe that there is a fundamental mistake in the program of those who advocate it. Science is not advanced by any method which can be represented as inference from the data of sense by application of universally valid rules, and it has no presuppositions of the sort discussed in the older manuals of induction.

Scientists are always concerned with the elaboration and testing of hypotheses which may conceivably be refuted by further experience, and their attitude is scientific only in so far as they are prepared to admit this. If at any time they put forward theories

for which they refuse to admit the conceivability of falsification, they have abandoned scientific method, even though they may produce masses of evidence which is supposed to be confirmatory. It has been alleged in particular that dialectical materialists and psychoanalysts, in spite of their pretensions to be called scientists, are guilty of such obscurantism. On the other hand we can reasonably say that the scientific enterprise is a search not only for special uniformities (*i.e.*, regularities expressible in empirical generalizations) but also for uniformity in the sense of theoretical simplicity. James Clerk Maxwell, for example, is accounted a very great scientist not because of any work which he did in Baconian fashion but because he showed how the separate studies of heat, light, magnetism, and electricity could be united in one elegant theory. It is impossible, of course, to say in advance what success will be achieved in the search for conceptual simplicity, but it is interesting to notice two different ways in which scientists have tried to get what they want.

The first method is by concentration of attention on those features of the world which seem to admit of mathematical treatment; *i.e.*, on the so-called primary qualities of things (number, shape, size, and motion or rest), in distinction from the secondary qualities (warmth, colour, taste, smell, etc.) which are correlative to our special senses and were described by Locke as the powers of bodies to produce sensations in us by the action of their minute parts on our sense organs. This concentration of attention began already in antiquity when Democritus put forward his theory of atoms, and it is the principle of the demarcation of physics as that science has been studied since the 17th century. Though the hypotheses of secondary induction favoured by 20th-century physicists differ greatly from those formulated 300 years earlier, they are still in terms of primary qualities.

Theoretical physics is essentially mathematical physics, and it was even maintained by Einstein that the ideal of physical explanation should be the geometrization of the basic laws of nature. Einstein meant by this, not that physics could be developed *a priori* as a branch of pure mathematics (which is perhaps what Descartes hoped), but rather that it might be possible to choose from among the abstract geometries discussed by pure mathematicians one which in application to nature would provide a unified field theory of all forces. He did in fact geometrize the law of gravitation within his general theory of relativity, but the prospect of the geometrization of all the fundamental laws of physics seems much more remote now than when he first conceived his ideal. Obviously the unification and simplification of science which can be achieved by the method characteristic of physics is not available for dealing with those events which have been deliberately excluded from the realm of physics, namely experiences.

The second general method of simplifying our scientific picture is that of presenting less fundamental regularities in nature as logical consequences from the conjunction of more fundamental regularities with initial conditions of a historical or geographical kind. Evolutionary explanations are of this pattern. They were tried first in humane studies during the 18th century, and from there passed in the 19th to biology. In the 20th century they have appeared even within physical science. It is now customary, for example, to think of atoms, planets, stars, and galaxies as relatively stable products of a process of cosmic evolution. Within this grand scheme it is natural to think of the occurrence of sense experiences as connected with the appearance of organisms of a certain complexity; but we have as yet no explanation of the novelty, and if, in the phrase favoured by some biologists and philosophers, we describe it as a case of emergence (*q.v.*), we do no more than label the problem.

The Scope of Scientific Method.—The prestige acquired by physics, chemistry and physiology from the middle of the 19th century became so great that there have been many attempts to apply the methods of these sciences in other fields. These efforts have in turn provoked attempts to erect barriers beyond which scientists should not presume to go. In particular there has been much talk of demarcating a boundary between the proper spheres of science and of religion. It is desirable therefore to consider the scope of scientific method; *i.e.*, whether there are any limits to its application.

Because the various special sciences have all been separated successively from the matrix of philosophy (*q.v.*), those who advocate the application of scientific method to new fields sometimes think of themselves as liberators and champions of enlightenment against obscurantism. At times the attitude of professional philosophers toward science may perhaps have given some justification for this view; but in general it is a mistake to think of philosophy as opposed to science. For in the past the word "philosophy" was used, as we have seen, to cover all that is now called science, and in its more restricted modern usage it signifies the search for clarity by the study of the relation of concepts. So long as scientific advance does not involve the asking of any questions about the relations of concepts of high generality science has little, if any, contact with philosophy in the modern sense, and those who are actively engaged in the advance may come to think of philosophical inquiries as fruitless and even perverse. This was the situation in chemistry, for example, at the beginning of the 20th century. But when the development of scientific theory leads to suggestions which are at variance with common sense or at least so far removed from the realm of common sense that they cannot be illuminated by familiar analogies, scientists themselves say that their work has a philosophical aspect; *i.e.*, that it involves clarification of concepts. This happened in physics with the appearance of the relativity and quantum theories.

Conversely, philosophers of the 20th century who are especially interested in the progress of science have sometimes described their work as scientific. Bertrand Russell, for example, published in 1914 a book entitled *Our Knowledge of the External World as a Field for Scientific Method in Philosophy*, and thereafter the phrase "scientific philosophy" occurred often in philosophical literature. This way of speaking seems, however, to involve an unjustified extension of the use of the word "scientific." Those who adopt it wish no doubt to convey the impression that the philosophy which they favour is a permanent intellectual acquisition and not merely the product of a fashion or the expression of personal attitude. But there is usually no difficulty in distinguishing the conceptual inquiries of the philosopher from the empirical researches of the natural scientist, and there is nothing to be gained from a blurring of the distinction.

When we say that psychology and sociology are empirical sciences, rather than departments of philosophy in the modern sense of that word, what we have chiefly in mind is the possibility of using primary induction in these studies. But those who issued the first declarations of independence on behalf of these studies sometimes revealed in their claims an extravagance like that which is too often found in political nationalism. Thus Émile Durkheim maintained in his *Règles de la méthode sociologique* (1894) that sociological laws were not reducible to those of any other science; and in psychology also it has sometimes been held that explanation can be achieved only by the introduction of hypotheses which are themselves purely psychological. It is clear that for research to be practicable there must be a division of academic labour and that there can be no specialization without the distinction of one science from another. But this does not entail the denial of all possibility of co-operation or require that the distinction between primary and secondary induction, which is of the greatest importance in physics, should reappear separately in all other branches of science. There may of course be principles of explanation other than those of physics, but the question whether the laws of one department of science can be explained by reference to those of another is to be settled in each case by scientific inquiry, not by *a priori* pronouncements from separatists or universalists.

Since psychology and sociology have been recognized as sciences it is sometimes asked whether scientific method can be applied in the study of human history. This is a confusing question. Those who ask it may perhaps mean by "scientific method" no more than the use of modern techniques such as the radio-carbon method of dating a wooden object. Or again they may mean simply a dispassionate and unprejudiced approach to controversial issues. In either case the answer is "Yes." If, however, the questioners wish

to know whether history can become a branch of science, the answer seems to be that history cannot be a science like physics, chemistry or even sociology, since it deals with individual persons and events, but that it may be scientific in the same sense as astronomy and geography, which also apply generalizations to individual objects; and that in a way already noticed it may provide evolutionary explanations of certain generalizations about human behaviour (*e.g.*, in anthropology and philology).

In all ages history has in fact exhibited the patterns of explanation favoured by its authors. When men believed in magic, their history was full of magical causation. When it was the ideal of explanation to relate everything to the divine purpose, history was conceived as theodicy or the tracing of God's plan. When in the second half of the 19th century the principle of the survival of the fittest was thought to be the supreme principle of explanation in all biology, there were soon historians ready to apply it in their accounts of the vicissitudes of men and societies.

In all this there is nothing to indicate any need for drawing a boundary to the application of scientific method. On the contrary, it seems absurd even to suggest that there might be such a boundary within the realm of fact as opposed to value. For whenever we make an assertion that cannot be checked either by hard thinking alone or by observation alone, we commit ourselves to judgment by scientific method. This is not to say that we cannot reasonably support any of our statements by appeal to authority, but rather that in this field all rationality, including the rationality of relying on any authority, depends in the last resort on the rationality of scientific method as described above. For even those who cite miracles as evidence of the reliability of their authority assume premisses derived from induction, as for example that events of certain sorts do not happen without divine intervention.

Valuations as opposed to statements of fact are not established by scientific method. This is indeed a truism, and if we wish to speak of a limit to the applicability of scientific method we may perhaps say that we have found it here. But we must be cautious in the way in which we draw the boundary. For discoveries made by scientific method are undoubtedly relevant to some of our valuations. Although chemical analysis of an artist's materials does not contribute to an aesthetic judgment of his work, scientific knowledge about the consequences of a man's act may be of the greatest importance for a moral judgment of its rightness. What we must guard against here is the suggestion that moral distinctions are meaningless unless they can be identified completely with distinctions of the sort that scientists can study.

SCILLY ISLES, a group of about 140 small islands and islets, lying off Cornwall, Eng., 21–31 mi. (34–50 km.) W by S of Land's End. The origin of their name has never been authoritatively settled (possibly from the Cornish *Silya* "conger eel"); they are thought to be the Cassiterides (Tin Islands) of the Phoenicians, Greeks, and Romans, and the Silures of the Romans. The true islands number 48 with an area 6.3 sq.mi. (16.3 sq.km.). Apart from the 5 inhabited islands, 18 are capable of bearing grass, and 25 are barren. The larger islands vary in height from a little below to a little above 100 ft., the highest point, 166 ft., being found on St. Mary's. The islands are wild and picturesque, with sheer cliffs and many large caves hollowed out by the Atlantic. Because of the reefs and shoals by which these shores are surrounded, navigation becomes perilous in rough weather and on an outlying rock to the southwest is Bishop Light, first built, with infinite difficulty, in 1858; other lighthouses are on Round Island and Penninis Head (St. Mary's). The islands are part of an almost submerged granite mass that has been broken up by the sea. This mass was probably joined to the mainland between the Armorican folding and the Upper Cretaceous periods, but during Pliocene times it was submerged, since when there has been an elevation from time to time as can be seen in the raised beaches and the terracing of the rocks. According to legend, the Scilly Isles are the only visible remains of the land of Lyonnesse (*q.v.*). It is interesting to note that Solinus, the Latin grammarian and compiler, in A.D. 240 and Sulpicius Severus, the Christian writer, in 400 spoke of the Scillies in the singular, "Siluram Insulam." Some of the islands, *e.g.*, St. Agnes and Gugh, are joined together by bars of shingle and blown sand, and St. Mary's really consists of three islands joined by sand bars. Olaf I Trygvesson (*q.v.*) in his saga tells of his visit to the Scillies in the 10th century and his conversion there to Christianity, which he then introduced to Scandinavia.

The climate of the islands is unusually mild, the range of temperature being from 8° to 14° C (46° to 58° F). Snow is rarely seen. Fuchsias, geraniums, and myrtles attain an immense size, and aloes, cactus, and prickly pear flourish in the open. The gardens of the governor on Tresco Island are subtropical in character. The raising of early asparagus, spring vegetables, and flowers is the principal industry. From the start of flower growing in 1881 and a recorded figure of 65 tons of cut flowers in 1885, this trade had expanded by the mid-1960s to more than 1,200 tons, representing 60,000,000 blooms. The acreage under flowers in the mid-1960s was 582. Grown in the open air in winter, protected from the Atlantic gales by hedges, the Scilly flowers are more popular than those forced under glass. The islands are of great biological interest. They lie farther south than the rest of Great Britain and with their milder climate have a flora and fauna akin to those of the European continent. Three species of wild plant are found in the isles and nowhere else in Britain. The Scilly shrew mouse *Crocidura cassiteridum*, although not related to any species in Britain, is closely related to a species found in France. Among the immense variety of sea birds, the roseate tern is the rarest British breeding tern and the Manx shearwater has its only British breeding site in the islands. In 1957 the Nature Conservancy, the Duchy of Cornwall, and Lt.-Commander T. M. Dorrien-Smith, the lessee, agreed to treat many of the uninhabited islands as a "Site of Special Scientific Interest."

The inhabited islands are St. Mary's, Tresco, St. Martin's, St. Agnes, and Bryher. The total population in 1961 was 2,288, of which 1,736 lived on St. Mary's. Hugh Town, St. Mary's, is the capital, occupying a sandy peninsula. The town possesses a harbour and a roadstead where large vessels can lie at anchor. Governed by a unique type of county council, the islands are part of the St. Ives parliamentary division of Cornwall. They are served by steamers from Penzance and by air from St. Just, and there is radio and cable communication with the mainland.

On Tresco there are ruins of an abbey and of two fortifications called Oliver Cromwell's Tower and King Charles's Tower. Rude pillars and circles of stones and barrows are common, the most remarkable being a barrow on the Isle of Samson, 58 ft. in girth and containing a very perfect kistvaen, or sepulchral chamber of stone. There is no written evidence concerning the Scillies until the reign of Henry I. The king gave the isles to the abbot and Church of Tavistock (Devon), and secular priests were temporarily substituted for regulars by the abbot in 1345. Sharing the dignity of lords of Scilly with the abbot was the family of Blanchminster (de Albo Monasterio) in the reign of Edward I. Ralph de Blanchminster held of the earldom of Cornwall lands in Scilly at a yearly service of 300 puffins in 1345. In 1484 value of the lands was estimated at 40*s*. in time of peace and nothing in time of war. The Blanchminsters resisted and imprisoned the coroner of Cornwall and in 1319 were granted a coroner of their own. In 1547 Silvester Danvers, a co-heir of the Blanchminsters, sold his moiety of Scilly to Sir Thomas Seymour, by whose attainder in 1549 it fell to the crown, which already possessed the church land and revenues. In 1571 Elizabeth I leased the islands for £10 a year to Francis Godolphin, who built Star Castle above Hugh Town in 1593. During the Civil War, Hugh Town gave shelter to Prince Charles until his escape to Jersey in 1646. The islands were occupied by Roundheads for two years, but in 1648 declared for the king with Sir John Grenville as governor. After Grenville's surrender to Adm. Robert Blake in 1651, Cromwell's Tower was built on Tresco. Early a haunt of pirates, the islands were afterward notorious for smuggling. In 1834 Augustus Smith succeeded the

Godolphins as lessee and introduced compulsory education and other measures to improve the condition of the inhabitants. His nephew, T. A. Smith-Dorrien-Smith, succeeded him in 1872, and in 1933 A. A. Dorrien-Smith, the latter's son, surrendered to the Duchy of Cornwall the four islands of St. Mary's, St. Martin's, St. Agnes, and Bryher, retaining the others on a 99-year lease.

SCIPIO (originally meaning "staff"), the name of a patrician branch of the *gens Cornelia* in ancient Rome. The most important Scipios are given below. Others include Lucius Cornelius Scipio Barbatus (consul 298 B.C.) and his son Lucius Cornelius Scipio (consul 259, censor 258) who attacked Corsica in 259; both were buried in the "Tomb of the Scipios" outside Rome on the Appian Way.

Publius Cornelius Scipio (d. 211 B.C.), consul in 218, sailed with an army to southern Gaul to prevent Hannibal's advance on Italy (*see* Hannibal). Having arrived too late, he himself returned to Italy but boldly sent his army on to Spain under his elder brother Gnaeus to check the Carthaginian forces still there. In northern Italy he hoped to fight delaying actions against Hannibal along the tributaries of the Po. Being repulsed and wounded at the Ticinus, he retired to the Trebia where he was joined by his colleague Tiberius Sempronius Longus, who insisted on fighting and was defeated (December 218; *see* Trebbia).

In 217 Scipio was sent as proconsul to Spain; in a battle near the Ebro he and his brother smashed Hasdrubal's attempt to break through to Italy (215), and by 212 they had captured Saguntum (modern Sagunto). From this base they could move farther south; advancing separately, however, they both met disaster and death, Publius on the upper Baetis (Guadalquivir), Gnaeus in the hinterland of Carthago Nova (Cartagena) (211). In spite of this final defeat, they had for seven years denied Hannibal the resources of Spain.

Publius Cornelius Scipio, surnamed Africanus, the elder (236–184/183 B.C.), son of the Publius above, is said to have saved his father's life at the engagement on the Ticinus and, as military tribune, to have strengthened Roman resistance to Hannibal after the Carthaginian victory at the Battle of Cannae (216). After his curule aedileship (213), though only a *privatus* (having been neither praetor nor consul), he was, without constitutional precedent, appointed by the Roman people to a proconsular command in Spain in the year after his father's death. There, though all south of the Ebro was in Carthaginian hands, he boldly continued his father's offensive strategy.

By a brilliant swoop Scipio in 209 captured the enemy's headquarters, Carthago Nova, from which all three Carthaginian armies in Spain happened to be ten days' distant; there he gained stores and supplies, Spanish hostages, the local silver mines, a splendid harbour, and a base for advance farther south. After training his army in new tactics he defeated Hasdrubal Barca at Baecula (Bailén) in Baetica (208); whereas normally the two rear ranks of a Roman army closely supported the front line, Scipio in this battle, under a screen of light troops, divided his main forces, which fell on the enemy's flanks. When Hasdrubal broke away, ultimately to join his brother Hannibal in Italy, Scipio wisely declined the impossible task of trying to stop him and decided rather to accomplish his mission in Spain, the defeat of the other two Carthaginian armies still there. This he brilliantly achieved in 206 at the Battle of Ilipa (*q.v.*; Alcalá del Río, near Seville), where he held the enemy's main forces while the wings outflanked them. He then secured Gades (Cádiz), thus making Roman control of Spain complete.

PUBLIUS CORNELIUS SCIPIO AFRICANUS THE ELDER, PORTRAIT ON A SILVER COIN FROM CARTHAGO NOVA

Elected consul for 205, Scipio boldly determined to disregard Hannibal in Italy and to strike at Africa. Having beaten down political opposition in the Senate, he crossed to Sicily with an army consisting partly of volunteers. In 204 he landed with perhaps 35,000 men in Africa, where he besieged Utica. Early in 203 he burned the camps of Hasdrubal Gisco and his Numidian ally Syphax. Then, sweeping down on the forces which the enemy were trying to muster at the Great Plains on the upper Bagradas (modern Souk el Khemis, on the Medjerda, in Tunisia), he smashed their army by a double outflanking movement.

After his capture of Tunis the Carthaginians sought peace terms, but Hannibal's subsequent return to Africa led to their renewing the war in 202. Scipio advanced southwestward to join the Numidian prince Masinissa (*q.v.*), who was bringing his invaluable cavalry to his support. Then he turned eastward to face Hannibal at the Battle of Zama (*q.v.*); his outflanking tactics failed against the master from whom he had learned them, but the issue was decided when the Roman and Numidian cavalry, having broken off their pursuit of the Punic horsemen, fell on the rear of Hannibal's army. Victory was complete and the long war ended; Scipio granted comparatively lenient terms to Carthage. He was named in honour Africanus. (*See* also Punic Wars.)

In 199 Scipio was censor and became *princeps senatus*. Though he vigorously supported a philhellenic policy, he argued during his second consulship (194) against a complete Roman evacuation of Greece after the ejection of Philip V of Macedonia, fearing that Antiochus III of Syria would invade it; his fear was premature, but not unfounded. In 193 he served on an embassy to Africa and perhaps also to the east. After Antiochus had advanced into Greece and had been ejected by a Roman army, Scipio's brother Lucius was given the command against him, Publius serving as his legate (190); together the brothers crossed to Asia, but Publius was too ill to take a personal part in Lucius' victory over Antiochus at Magnesia (for which Lucius took the name Asiagenus). (*See* also Antiochus: *Antiochus III the Great.*)

Meantime in Rome Scipio's political opponents, led by the elder Cato, launched a series of attacks on the Scipios and their friends. Lucius' command was not prolonged; the generous peace terms which Africanus proposed for Antiochus were harshly modified; and the "trials of the Scipios" followed. On the trials the ancient evidence is confusing: in 187 an attack on Lucius for refusing to account for 500 talents received from Antiochus (as war indemnity or personal booty?) was parried; and Africanus himself may have been accused, but not condemned, in 184. Anyhow, his influence was shaken and he withdrew from Rome to Liternum in Campania, where, embittered and ill, he died (184/183).

Scipio married Aemilia, daughter of the consul L. Aemilius Paullus (Paulus) who fell at Cannae. He had two sons (Publius, debarred by ill health from a public career, adoptive father of Scipio Aemilianus; and Lucius, praetor in 174) and two daughters, one of whom became the mother of the Gracchi. A man of wide sympathies, cultured and magnanimous, Scipio easily won the friendship of such men as Philip of Macedonia and native princes in Spain and Africa, while he secured the devotion of his own troops. Though essentially a man of action, he was also something of a mystic in whom contemporary legend saw the favoured of Juppiter Capitolinus as well as a spiritual descendant of Alexander the Great. One of the greatest soldiers of the ancient world, by his tactical reforms and strategic insight he created an army which defeated even Hannibal and asserted Rome's supremacy in Spain, Africa, and the Hellenistic east. His Greek sympathies led him to champion Rome's mission in the world as protector of Greek culture; he preferred to establish Roman protection rather than direct conquest and annexation. For ten years (210–201) he had commanded a devoted army at the people's wish; but, though convinced of his own powers, he offered no challenge to the dominance of the Roman nobility ensconced in the Senate, except by normal political methods (in which he showed no outstanding ability). Reaction against his generous foreign policy and against his en-

couragement of Greek culture in Roman life led to his downfall amid personal and political rivalries, but his career had shown that Rome's destiny was to be a Mediterranean, not merely an Italian, power.

PUBLIUS CORNELIUS SCIPIO AEMILIANUS, surnamed AFRICANUS (the younger) and NUMANTINUS (185/184–129 B.C.), was the younger son of the general L. Aemilius Paulus (*q.v.*), under whom he served at the Battle of Pydna (*q.v.*) in 168 B.C. He was adopted by the elder son of Scipio Africanus, Publius, whose name he assumed. His early years are described by Polybius, who gained his friendship. In 151, when the Romans had met with defeats in Spain, he volunteered for service there as military tribune; his integrity, personal bravery and honest diplomacy, reminiscent of the qualities of his adoptive grandfather, were appreciated by Spanish tribes long sickened by Roman treachery.

In 150, when on a military mission to Masinissa, he was asked by the Carthaginians to mediate in their war against Masinissa, but he achieved no result. In the following year, after Rome had declared war on Carthage, he served in Africa as military tribune with conspicuous ability, and in 148 Masinissa, at the point of death, asked him to arrange the future of Numidia; Scipio divided it among the king's three sons. Returning to Rome to stand for the aedileship, he was by a special vote of the people elected to the consulship of 147 and was granted the command against Carthage. Scipio returned to Africa with his friend Gaius Laelius and possibly also Panaetius. He blockaded Carthage and in 146 destroyed the city, enslaving the survivors and establishing the province of Africa. He celebrated a triumph and received the name of Africanus (Minor).

His censorship in 142 was marked by traditional sternness. Tiberius Claudius Asellio, whom he demoted from the equites, prosecuted him in 140. Accompanied by Panaetius, he served on an embassy to Egypt, Syria, Pergamum, and Greece (140–139). On his return he prosecuted L. Aurelius Cotta for extortion (138) and supported a measure to introduce secret ballot in judicial assemblies of the people (137). Military disasters and inefficiency in Spain required the dispatch of a capable soldier; to this end, since reelection to the consulship had been forbidden in 151, by special dispensation he was elected consul for 134. After reestablishing discipline in the Roman army he brought the war in Spain to an end by the blockade and destruction of Numantia in 133 (traces of his camps and earthworks there still survive) and received the additional cognomen Numantinus.

He returned to Rome after the death of his cousin and brother-in-law Tiberius Gracchus, but expressed disapproval of his unconstitutional behaviour, quoting the *Odyssey* (i, 47): "So perish all who do the like again." He opposed a proposal of the tribune Gaius Papirius Carbo to allow the reelection of tribunes (131 or 130), thus increasing his unpopularity with the masses, who naturally had resented his attitude to Gracchus. In 129 he carried a measure which affected the working of the Gracchan land commissioners, probably, however, only warning them off public land held by the allies in order to avoid "international" issues. The night before he was to have spoken on the agrarian laws he died in mysterious circumstances: various persons were later suspected of murder, or even Scipio himself of suicide, but very probably he died a natural death.

An admirer of Greek literature and learning, he gathered around him the so-called "Scipionic circle," a coterie which included Polybius, Panaetius, Lucilius, Terence, and Laelius and aimed at blending the better elements of Greek and Roman life. Upright himself, he tried to revive and uphold earlier Roman standards of conduct. His thought, Stoic in philosophy, moved on traditional lines, and he tried to maintain Rome's accustomed relations toward the Italian allies and the provinces. An able soldier and orator, he acted as a moderating influence on the constitutional difficulties of his day which increased after his death. Cicero, who made him the chief speaker in his *De Republica*, regarded his era as the golden age of aristocratic government.

SCISSORS AND SHEARS, cutting instruments having two blades, usually pivoted to meet and cut as the handles at their ends close. The terms scissors and shears are nearly synonymous, although "shears" sometimes denotes larger size. Modern scissors and shears derive from two basic types: spring shears, in which the blades are connected by a C-shaped spring at the shank (handle) ends; and pivoted scissors and shears, in which the connection is made by a rivet or screw located between the handles and the blades. The spring type, probably dating to the Bronze Age, was commonly used in Europe until the end of the Middle Ages. Pivoted bronze and iron scissors and shears were used in ancient Rome and in China, Japan, and Korea. Their domestic use in Europe dates from the 16th century, but they were not in common use until the 17th century. Large-scale production of pivoted scissors and shears began in 1761, when Robert Hinchliffe of Sheffield, Eng., first used cast steel in their manufacture. Ornamental scissors with elaborately designed handles were numerous in the 19th century, and much hand-forged and beautifully decorated work was produced for the Great Exhibition in London in 1851.

By the end of the 19th century mechanical methods of production had begun to simplify styles and patterns. The blanks (unfinished pieces) for scissors are made now by high-speed forging of red-hot steel bars between the dies of drop hammers. For ordinary scissors, steel containing 0.55% carbon is mainly used; for the finest scissors and shears for trade use (such as tailors' shears and trimmers) a harder steel containing 0.75% carbon is preferred. For cutting man-made fibres, which are harder and more blunting than natural fibres, the blades of tailors' shears are sometimes made of a composite material consisting of an even harder steel on the cutting side (1.03% carbon), backed by tough iron. Many scissors, including surgical varieties, are made of stainless steel (*q.v.*), and some specialized scissors and shears are made of nonferrous alloys that will not produce a spark or interfere with magnetism (*e.g.*, for cutting cordite and magnetic tape). Very cheap scissors are made from relatively soft steel wire that is pressed cold and is not hardened. In most cases the blanks for the handles and blades of scissors are one piece, but for comfortable use of large shears and some specialized scissors the handles are made of malleable metal and are accurately positioned with, and electrically welded to, the steel blades. Pinking-shear blades may be fitted to aluminum-alloy handles to reduce weight. As the process of cold forging progresses and suitable cold-forging steels are produced, some scissors of satisfactory quality may be made from cold-forged blanks.

If scissors are to cut well, the blades should touch in two places only—at the joint and at a single spot along the blades, wherever the cutting is taking place. The blades are made to twist or curve toward one another, and, when completely closed, the points of the blades should touch. Also, both blades must be accurately tempered to equal hardness. In the finest scissors and shears, the two blanks and the screw (the nut also in the case of large shears) are coded with an identification mark early in manufacturing to ensure their being treated as a set.

The blades of scissors and shears require sharpening by experts. Each blade is passed lightly across a grinding wheel to restore the sharpness of the edge-angle. The grinding process has

to follow the twist of the blade and has to be done smoothly and continuously with an even pressure throughout the whole stroke to avoid causing any ridge or other irregularity in the edge. Inexpert treatment, such as grinding the insides of the blades, will ruin them; their cutting life may be prolonged, however, by gently rubbing the inside edges of the blades with the fingers to remove particles of material, dust, etc., and by not using scissors or shears for purposes beyond their strength. *See* also CUTLERY.

See G. I. H. Lloyd, *The Cutlery Trades* (1913); J. B. Himsworth, *The Story of Cutlery from Flint to Stainless Steel* (1953).
(A. E. HA.)

SCOLECITE, a zeolite mineral of the natrolite group. It is a hydrated silicate of lime and alumina. It commonly occurs as bundles of radiating fibres and when heated sometimes curls up like a worm; the name is derived from the Greek word meaning a worm. It is usually colourless or white and more or less transparent. It crystallizes in the monoclinic system, with angles very near those of the cube. Scolecite occurs frequently with other zeolites in the western isles of Scotland, Iceland, in the Deccan trap area in India and at Table mountain, Colo., among many other localities.

For composition, structure, etc., *see* ZEOLITE.

SCONE, a civil parish of the county of Perth, Scot., containing Old Scone, the site of a historic abbey and palace, and New Scone, a modern village, about 2 mi. NNE of Perth, near the left bank of the Tay. Pop. (1961) 3,713.

According to tradition Scone became the capital of "Pictavia" in succession to Forteviot in the 8th century and remained that of Alban after the union of Picts and Scots. In 906 Constantine III and Bishop Cellach held a council concerning the church on the Mote hill of Scone, hence also called Hill of Worship. Kenneth MacAlpin is said to have brought from Dunstaffnage the Stone of Destiny, on which Scottish kings were crowned until its removal to Westminster abbey by Edward I of England. A Culdee foundation which existed there from early times was superseded by an Augustinian house founded by Alexander I *c.* 1115. Scone remained the normal place of the coronation of Scottish kings, the last being that of Charles II in 1651. It was also the scene of many medieval parliaments.

At the Reformation the abbey was burned by a mob from Perth and the lands were given to the earl of Gowrie. On the Gowrie forfeiture in 1600 these were granted to Sir David Murray of Gospertie, afterward Viscount Stormont, to whose descendant, the earl of Mansfield, the estate still belongs. Sir David completed the mansion begun by Gowrie, but it was pulled down in 1803 to make room for the present house.

A church built on the Mote hill in 1604 was demolished in the late 18th century, except for one aisle. Scone was visited by James Edward Stewart in 1716 and by Prince Charlie in 1745. The old cross of Scone stands in the park, which also contains a racecourse.
(E. W.-M. B.-M.)

SCOPAS of Paros, sculptor and architect, was considered by ancient writers one of the greatest artists of the 4th century B.C. He is said by Pliny to have worked on the sculptures of the mausoleum of Halicarnassus (*c.* 350 B.C.) together with Bryaxis, Timotheus and Leochares, and to have carved the reliefs on one of the columns of the temple of Artemis at Ephesus; and by Pausanias to have been the architect of the temple of Athena Alea at Tegea. Unfortunately, though sculptural remains of all three buildings have survived, none can with certainty be associated with Scopas. In the case of the mausoleum, there is the difficulty of apportioning the extant reliefs to four different artists of whose style little is known. In the case of the Ephesian temple only three of the 36 columns that Pliny says were decorated have survived. And the few battered pieces that remain of the pedimental sculptures of the temple at Tegea are not necessarily the work of Scopas, for Pausanias attributes to him only the cult statues of Asclepius and Hygieia. Nevertheless, since Scopas was the architect of the temple, it is possible that he also at least sketched the designs for the pediments; and since the extant heads show a highly individual and forceful style, they may give an idea of Scopas' work. The squarish form, the deep-sunk eyes and a strongly emotional quality have, therefore, been thought to be characteristic of Scopas.

Pausanias, Pliny, Strabo and other ancient writers mention and sometimes briefly describe a number of statues made by Scopas for Asia Minor, the Peloponnesus and Attica, and some of these works have been tentatively identified in Roman marble copies and in the reliefs on Roman coins. Among them are a bronze Aphrodite seated on a goat, an Apollo Smintheus, an Apollo Citharoedus, a Maenad, a group of Eros, Himeros and Pothos, and a large group of Achilles, Nereids and Tritons.

Scanty though our knowledge of Scopas is, it can be surmised from the little which remains that he, together with Praxiteles and Lysippus, were the outstanding sculptors of the middle and second half of the 4th century B.C., who imparted to their work a new grace and emotional quality and whose influence was felt for many generations.

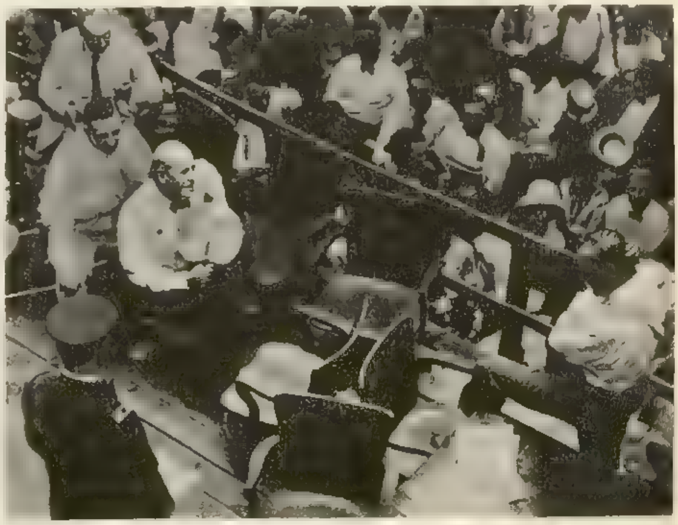
(G. M. A. R.)

SCOPES TRIAL, beginning July 10, 1925, at Dayton, Tenn., and ending July 21, was one of the most widely publicized legal cases in 20th-century U.S. history. The charge was that John Thomas Scopes, a teacher of science in Rhea high school in Dayton, had violated the Tennessee state law prohibiting the teaching in public schools of any theories that deny the divine creation of man as taught in the Bible. The basis for the sensational nature of the trial was laid by the increasing alarm of a Christian movement, known as Fundamentalism (*q.v.*), over the challenge of science and evolutionary theory to a literal interpretation of the Scriptures.

The legislature of the state of Tennessee was the first to pass an antievolution law, by an overwhelming majority (95–11), and the measure was signed by the governor on March 13, 1925. The essential section stated that it was "unlawful for any teacher in any of the universities, normals and all other public schools of the state, to teach any theory that denies the story of the divine creation of man as taught in the Bible, and to teach instead that man has descended from a lower order of animals."

When the American Civil Liberties union in New York city heard of the passage of the Tennessee law, the executive director Roger N. Baldwin sent a news release to leading Tennessee newspapers offering the services of the union to defend any teacher who would personally test the constitutionality of the statute by his classroom teaching. Baldwin soon received a telephone call from George Rapplyea, proprietor of a drug store in Dayton, stating that he had been discussing the offer with John Scopes. Al-



UNITED NEWSPICTURES

WILLIAM JENNINGS BRYAN (LEFT, WITH FAN) BEING CROSS-EXAMINED BY CLARENCE DARROW (RIGHT) DURING AN OUTDOOR SESSION OF THE TRIAL

though he had taught biology only briefly as a substitute, Scopes admitted to violating the law, and was indicted.

The leading lawyers on both sides were probably the most famous and the most appropriate who could have been produced. William Jennings Bryan (*q.v.*) came to Dayton to assist the prosecution. The defense was headed by Clarence S. Darrow (*q.v.*); the most famous criminal lawyer of his generation. He was assisted by Dudley Field Malone, a liberal Catholic and one of the great courtroom orators of the time, and by Arthur Garfield Hays, the outstanding civil liberties attorney of the day.

The dramatic nature of the case and the fame of the lawyers assured extended newspaper coverage. Each day that the case was in court about 175,000 words were telegraphed out of Dayton. The case was followed daily by tens of millions of readers in both the United States and Europe.

The rulings of the judge prevented any testing of the civil liberties issue of the constitutionality of the law or any testimony as to the validity of the doctrine of evolution. The sole relevant question, said the judge, was whether Scopes had actually taught the doctrine of evolution. The defense freely admitted that he had.

The case might, thus, have closed more rapidly had not Bryan made the serious mistake of permitting Darrow to get him on the stand and subject him to a long and grueling cross-examination as to his beliefs relative to the Fundamentalist attitude on science and biblical authority. The process, perhaps Darrow's most animated and sarcastic courtroom performance, was a devastating experience for Bryan; many believed it hastened his death, which occurred five days after the close of the trial. Darrow had adroitly used the judge's rulings on the irrelevance of the validity of the doctrine of evolution in the case to prevent Bryan from delivering a long oration he had prepared.

Scopes was convicted and fined $100. The defense appealed the case to the state supreme court which, in 1927, upheld the constitutionality of the 1925 law, but cleared Scopes on the ground that the lower court had exceeded its authority in fining Scopes $100. It thus turned out that the Scopes trial was more a contribution to public education on science and religion than a test of civil liberties.

SCOPOLAMINE (HYOSCINE) is an alkaloid drug obtained from a number of solanaceous plants including the deadly nightshade, henbane, and Jimson weed (*see* ALKALOIDS: *Detection and Preparation*). Scopolamine is the most active of the belladonna alkaloids, partly because of its greater solubility, which permits more rapid passage to the site of action. Like atropine, it has a depressant action on parasympathetic nerves and in larger doses on autonomic ganglia. It also has a marked depressant action on the central nervous system, and this is the basis of its main therapeutic uses. Combined with morphine it produces "twilight sleep," a state of analgesia and amnesia. This drug combination became popular for use during childbirth since the patient remains more or less conscious but does not usually recall later the unpleasant circumstances of the event. This and similar combinations are used for preoperative medication. Scopolamine taken orally is an effective remedy for motion sickness, probably because of its central depressant and its antispasmodic action. It also finds use in controlling the rigidity and tremor of parkinsonism. It is a toxic drug and is administered only in minute quantities. (V. E.)

SCORE (French, *partition;* Italian, *partitura;* German, *Partitur*) is the name given to the copy of a work of music containing the notation for one or many performers, and is so called from the way in which the music is divided by bars scored through the series of staves on which the music is written. In a solo work the score is the only copy of the notation. In concerted works the notation of each performer constitutes a part—*e.g.*, violin part, flute part—and a score shows the vertical alignment of each of the parts. Indications of both individual and simultaneous performance are thus provided for the principal performer, the conductor and the listener.

The word score is used in several specialized senses. The arrangement or reduction of an orchestral score for piano is commonly known as the piano score. A vocal score (of operas and choral works) consists of the vocal parts set out as in the full score, but with the orchestral score reduced for the piano. A short score is the sketch made by a composer for a full score, showing the main features set out on a few staves. An open score shows the parts, usually of a contrapuntal exercise, written on separate staves for greater clarity. A miniature score (or pocket score) is the published version of a full score reduced in size so as to be more convenient for study or following an orchestral work in performance.

The practice of writing music in score dates from the schools of polyphonic music in the early middle ages. It was replaced at the beginning of the 13th century by the choirbook—a large-size manuscript in which the soprano and alto parts usually faced each other on the upper halves of two opposite pages with the tenor and bass parts occupying the lower halves. This arrangement was considered economical since the upper parts, which sang the texts, required more space than the slow-moving lower parts. The music was read by the entire choir grouped around the choirbook set on a stand.

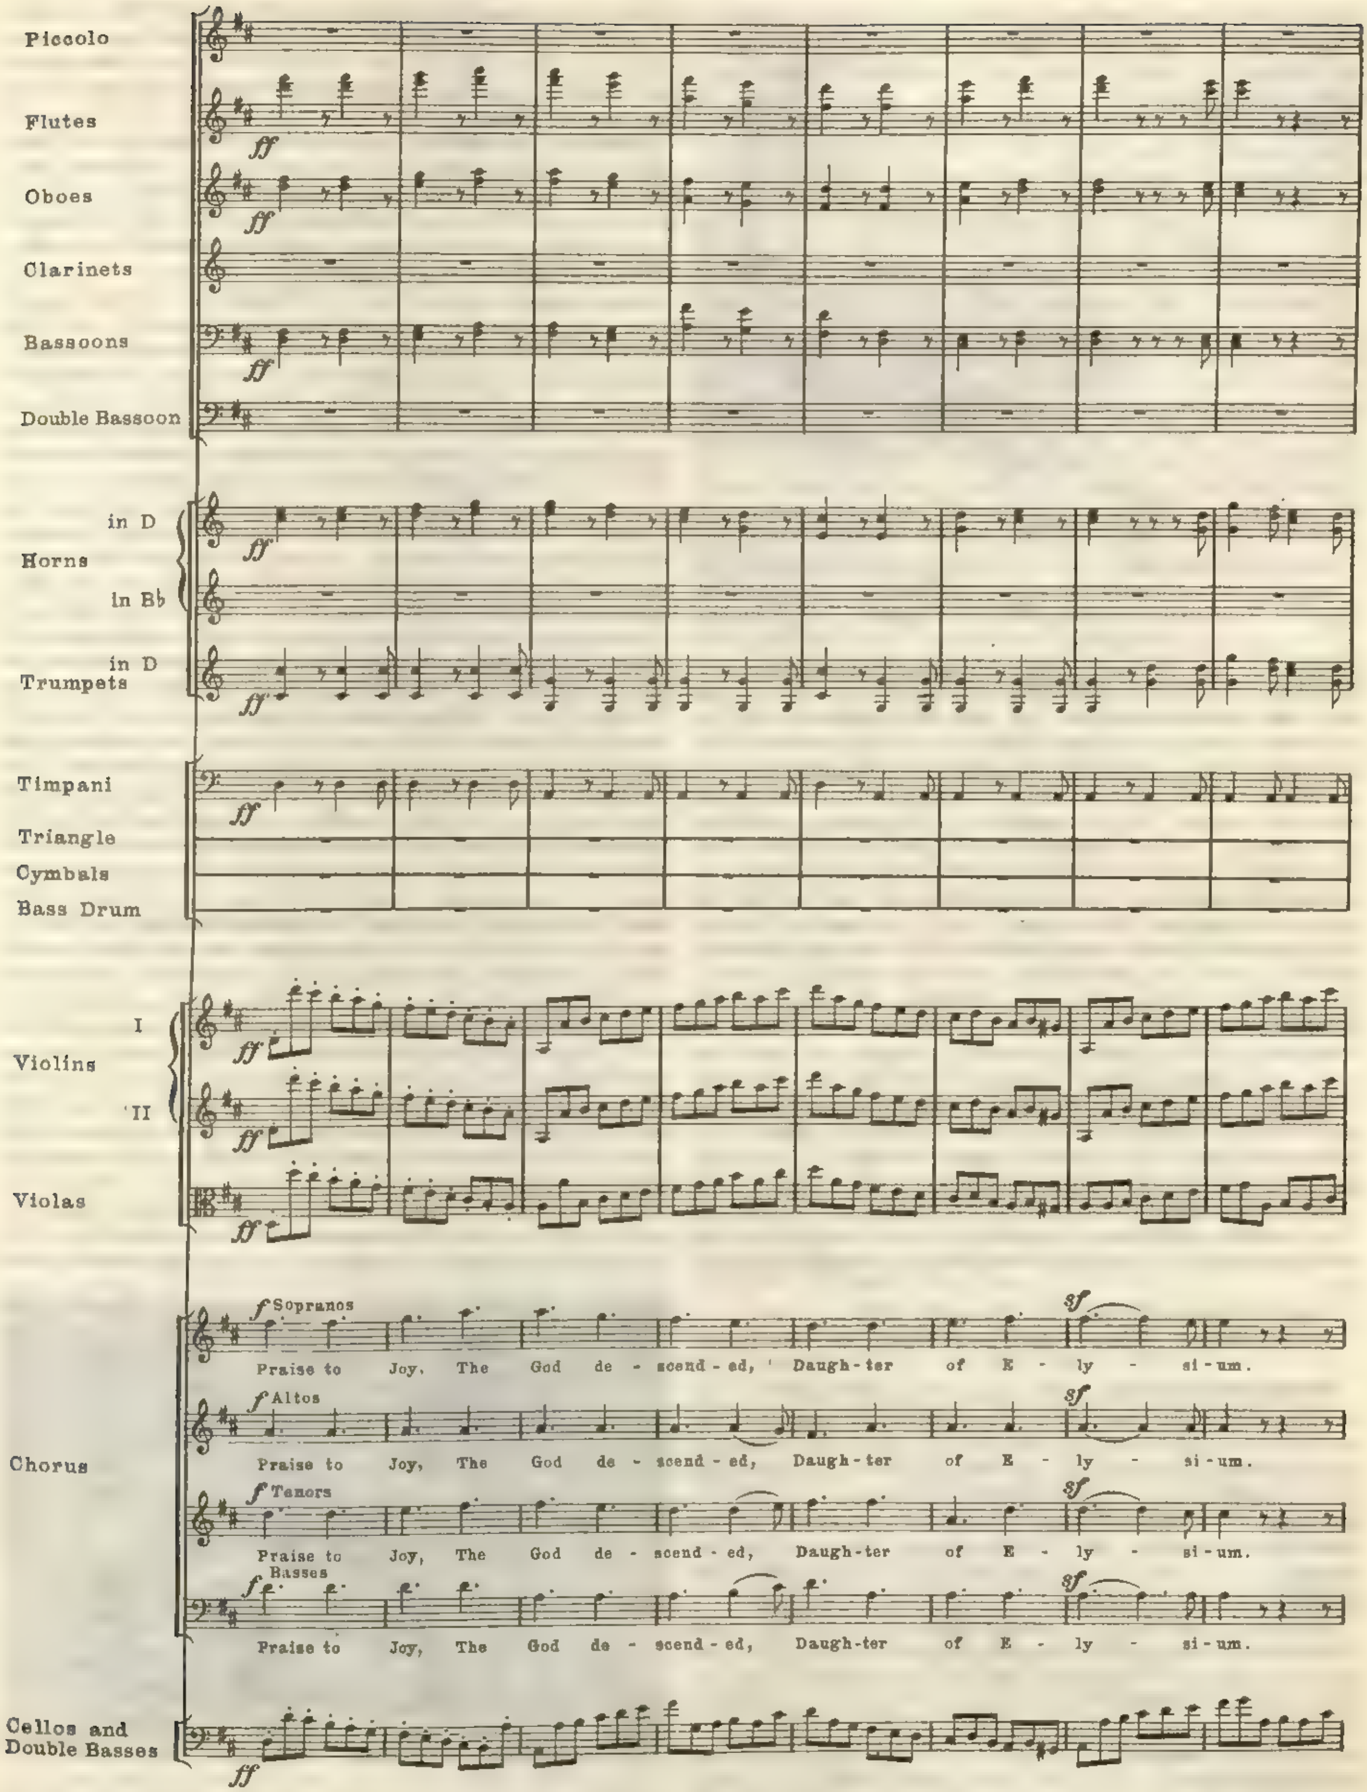
In the 15th and 16th centuries vocal and instrumental music was published in partbooks. These partbooks contained the notation of only single parts. The parts of madrigals were sometimes published crosswise on single sheets, which allowed each of the singers seated around a rectangular table to sing from his particular part.

The modern form of score, in which the bar lines are scored vertically throughout the parts, appeared in the 16th century in the madrigals of Cipriano de Rore and the orchestral music of Giovanni Gabrieli. In scores of all kinds the arrangement of the parts follows accepted schemes. In vocal works the arrangement from top to bottom is: soprano, alto, tenor, bass. Scores for unaccompanied choir in four parts are sometimes known as SATB scores. In scores of chamber works for string instruments the arrangement follows the compass of the instruments: first and second violins, viola, cello, double bass, with the part of a figured bass or a supporting keyboard instrument below. Parts for wind instruments in chamber works are placed above the strings in the same arrangement as that in the orchestral score, known as the full score.

The full score is divided from top to bottom into five main sections: woodwind instruments, brass, percussion, harps and keyboard instruments, and strings. The order followed for the woodwind is: flutes, oboes, clarinets and bassoons, with the higher and lower members of their families placed appropriately. In a work using a wide variety of instruments the woodwind section would thus be set out in this order: piccolo, flutes, bass flute; oboes, oboe d'amore, cor anglais, heckelphone; clarinet in E flat, clarinets in B flat or A, bass clarinet; bassoons, double bassoon. The order for the brass instruments is: horns, trumpets, trombones, tuba. The percussion section is headed by the part for timpani followed by the keyboard percussion instruments (glockenspiel, xylophone and vibraphone) and the instruments of indefinite pitch (triangle, cymbals, etc.), the latter requiring only a single line. The next section shows parts in double staves for harps, piano or organ. At the bottom of the score the string section is aligned as in chamber works.

In concertos the part of the solo instrument is placed immediately above the strings. In choral works the choral parts may appear either above the strings or, as in the illustration from the finale of Beethoven's *Choral Symphony*, between the viola and cello parts. In full scores of operas and oratorios solo parts appear above the choral parts. In military band scores the woodwind and brass are followed, in descending order, by string basses and percussion instruments. Brass band scores are usually arranged in the order of cornets, horns, baritones, trombones, euphonium and basses, and drums.

Score reading, which is part of the equipment of a conductor, consists of reproducing the essential features of a full score at the piano. It demands the ability to read simultaneously in the



SCORE OF THE FINALE OF THE CHORAL SYMPHONY (NO. 9 IN D MINOR) BY BEETHOVEN

alto and tenor clefs as well as the treble and bass clefs, and to transpose parts of many of the woodwind and brass instruments. Score reading of complex modern works is sometimes undertaken in the form of a piano duet.

Students of the orchestra and listeners generally find that the ear can be greatly helped by the eye in following the performance of orchestral and choral works with the score. This enables the general design of the work to be more easily grasped and ingredients of orchestral effects to be readily identified.

See G. Jacob, *How to Read a Score* (1944). (E. LR.)

SCORESBY, WILLIAM (1789–1857), English Arctic explorer, scientist and clergyman, who contributed particularly to the knowledge of terrestrial magnetism, was born near Whitby, Yorkshire, Oct. 5, 1789. His father, William Scoresby (1760–1829), made a fortune in the Arctic whale fishery. The son made his first voyage with his father when he was 10 years old, but on his return he was sent back to school until he was 14. After this he was his father's constant companion, and was with him on May 25, 1806, in the whaler "Resolution," when he reached 81° 30′ N lat. (19° E long.), then the highest latitude attained by a freely navigating ship.

Scoresby then attended the natural philosophy and chemistry classes at Edinburgh university and in his voyage of 1807 he began to study the meteorology and natural history of the polar regions. In 1811 his father resigned to him the command of the "Resolution," and in the same year he married. In a voyage two years later he established the fact that the temperature of the polar ocean is warmer at great depths than at the surface. He was elected a fellow of the Royal Society of Edinburgh in 1819 and about the same time he communicated a paper to the Royal Society of London "On the Anomaly in the Variation of the Magnetic Needle." In the following year he published *An Account of the Arctic Regions and Northern Whale Fishery*, in which he gathered the results of his own observations, as well as those of previous navigators. His voyage of 1822 to Greenland, during which he surveyed and charted 400 mi. of the east coast between 69° 30′ and 72° 30′, was the last of his Arctic voyages, for his wife had died while he was away and on his return he entered the church.

In 1824 the Royal society elected him a fellow and after two years at Cambridge he took his degree (1825) and was appointed to the curacy of Bessingby, Yorkshire. The discharge of his clerical duties at Bessingby, and later at Liverpool, at Exeter and at Bradford, did not prevent him from continuing his interest in science to which he added social questions, especially the improvement of conditions in factories. When crossing the Atlantic in 1848 he made some valuable observations on the height of waves and he voyaged to Australia in 1856 in order to obtain magnetic data.

Scoresby died at Torquay on March 21, 1857.

See R. E. Scoresby-Jackson, *The Life of William Scoresby* (1861). (L. M. FS.)

SCORPIO or SCORPIUS (the Scorpion), in astronomy, a constellation and sign of the zodiac. The constellation appears rather low in the south in the early evenings of summer for observers in middle northern latitudes. The stars outline a sprawling figure that might seem to suggest a scorpion or perhaps a kite with a long tail. The brightest star, Antares, is a supergiant at the distance of something like 170 light-years. This red star has several hundred times the sun's diameter and is intrinsically 1,000 times as luminous as the sun.

The region of the heavens from Scorpius eastward to Sagittarius and northward into Ophiuchus surrounds the direction of the centre of our galaxy. This region exhibits a spectacular display of star clouds of the Milky Way, star clusters including great globular clusters, and bright and dark nebulae. In photographs the dark cosmic dust is frequently illuminated by involved stars in patches of reflection nebulae, remindful of the glows around streetlamps on a foggy night. (R. H. BR.)

SCORPION, a venomous arachnid of the order Scorpiones. Although different in size and degree of toxicity, all scorpions are similar in appearance and are easily distinguished from spiders and other arachnids by their clawlike pincers and long upturned tail, at the tip of which is the characteristic sting. Because of their poisonous qualities, scorpions have been known and feared since ancient times.

Distribution.—While scorpions are usually associated with hot, tropical countries, they are not confined to them. In Europe, several species live in Greece, Italy, Spain, and the Balkans, and one ranges as far north as southern Germany. In the Western Hemisphere scorpions are found from the United States to Patagonia. They are absent from many islands.

Most scorpion species have a limited geographic range; *Isometrus maculatus*, found in all the warmer parts of the world, and *Scorpio maurus*, ranging from the Atlantic to India, are notable exceptions. A few scorpions are found at higher altitudes; *e.g.*, in the Atlas Mountains (northwest coastal Africa).

The species found in Europe and those in the United States are known and have been described. Of the four families represented in the United States, only the Buthidae, so far, have been shown to contain dangerously poisonous species, namely two species of the genus *Centruroides*. Other less dangerous species belonging to this genus are found in the U.S. Since less than a quarter of the more than 30 species known to occur in the U.S. have been studied with a view toward ascertaining the type and virulence of their poison, caution in handling all scorpions is advisable.

General Features.—The size of scorpions varies considerably. Some species are only 13 mm. (½ in.) long, while the largest attain 175 mm. (7 in.). Although even the smallest scorpions are large enough to be easily studied under low power magnification, the identification of species is quite difficult, because of the great deal of variation in most characters. The recent families into which the scorpions are divided, as well as the genera, are more easily determined, based on structural characters such as sternum, combs, spines, rows of granules on appendages and on the surface of the body, etc. Apparently of the least importance physiologically, these features were less subject to functional modifications and remained more or less stationary throughout long geological periods. Paleozoic scorpions, for example, are very much like recent ones in appearance. Specific characters are finer and less stable.

The second pair of appendages, the pedipalps, always held forward, are powerfully developed and are provided with pincers resembling the claws of a crayfish. The first portion of the abdomen, the preabdomen, is as wide as the cephalothorax. The last five annular segments form the "tail" or postabdomen, and are much more slender than and sharply set off from the preceding seven segments of the preabdomen. At the end of the tail is a sting, somewhat curved and pointed; its enlarged base contains a pair of poison glands, which open near the tip of the sting. Because of its curvature, the sting can be used only when the tail

ROBERT H. WRIGHT

FEMALE SCORPION (HADRURUS HIRSUTUS) SHOWING TWO PAIRS OF LATERAL EYES AND ONE PAIR OF MEDIAN EYES NEAR THE ANTERIOR EDGE OF THE CARAPACE. BENEATH THE CARAPACE ARE THE CLAWLIKE CHEWING MOUTHPARTS

is raised above the preabdomen and thrust forward. On the ventral side of the abdomen, immediately behind the genital operculum, there is a pair of comblike structures, the pectines. These organs are found only in scorpions. Each pectine articulates with a chitinous plate that represents the second sternite, and each is provided with muscles and nerves. The number of teeth, or lamellae, on each pectine varies from 3 to more than 40, depending upon the species and sex of the scorpion. It is thought that the pectines perceive ground vibrations.

Natural History.—*Habits.*—Scorpions live in a wide variety of places—under stones and bark, in crevices, under dead leaves and rubbish, in barns and deserted buildings, in thatched roofs, etc. They are usually nocturnal and prefer tight quarters.

Essentially inhabitants of warm areas, they tend to become sluggish during cold periods; they can, however, withstand freezing weather for several weeks. Although often common in dry areas, scorpions hide in the ground during arid periods. When the rains come, the scorpions find their way to the soil surface and stay under loose stones. They are very sensitive to microclimatic variations, and each species appears to live and reproduce within very limited and characteristic ecological conditions.

Some of the larger species (*e.g., Palamnaeus swammerdami* of southern India) emit rasplike sounds when alarmed. The noise is produced by a special stridulatory apparatus consisting of a spinous scraper on the flat outer face of the basal segment of the pedipalps and a tubercle-studded rasp on the flat inner face of the corresponding segment of the first pair of walking legs.

Food.—The food of scorpions consists of spiders, harvestmen, many different soft-bodied insects, myriapods, and even small mice. Scorpions probably do not actively seek their food, but rather wait for the prey to come to their lairs. The prey is picked to pieces by the chelicerae, the juices and soft tissues being drawn into the mouth by the pumping action of the pharynx. A well-fed scorpion can survive for several months without either food or water.

Enemies.—Notwithstanding their poison, scorpions have enemies. In tropical rain forests of Mexico and Central America, army ants, in the progress of their raids, can quickly overpower and dismember scorpions that they come upon. African baboons have been observed catching large scorpions, tearing off their tails, and greedily devouring the rest of the bodies. Lizards, snakes, and birds are listed among scorpion predators; furthermore, many scorpions are cannibals. It has also been reported that certain North African tribes enjoy eating live scorpions. Among parasites are various mites and nematodes. Actually, the greatest threats to the scorpion are food shortage, drought, and human activities.

Reproduction and Life Cycle.—When mature, the sexes show visible differences in the relative proportions of the body. The male is more slender and has a longer tail. It also has a pair of organs used in copulation, but these are visible only when the specimen is turned over on its back. When the male encounters a female, he engages her in a "courtship dance." The male grasps the female's pedipalpal claws with his and walks sidewards or backwards as he holds on to her. In *Buthotus alticola*, this promenade is preceded by a maneuver in which the animals, while facing one another, straighten the back parts of their bodies, compress the abdomens to the ground, and extend their tails upward. The tails are alternately twined and untwined, after which the animals promenade. This performance may last several hours. Finally, the male either digs a hole (while still holding the female) or finds a retreat into which the couple enter to copulate. Special organs in the male form a temporary penis with which the sperms are inserted. After copulation, the male is often attacked and devoured by the female.

The fertilized eggs develop inside the mother, and the young are born alive. The manner in which the eggs develop depends upon the amount of yolk present. Among the Buthidae, in which there is much yolk, the eggs pass into the oviduct and develop there; the embryos consume the yolk with which they are supplied. Among the Scorpionidae, with little yolk, the fertilized eggs remain in place and become closely mingled with the maternal tissues.

GORDON S. SMITH FROM NATIONAL AUDUBON SOCIETY

FEMALE SCORPION (HADRURUS HIRSUTUS) CARRYING YOUNG ON HER BACK

At birth the young, unable to take care of themselves, mount upon the mother's back. This process may be slow and laborious, for the newborn scorpions are very weak. The young may be so numerous as to hide the body of the mother so that only her appendages and tail are visible. In 10–16 days, after their first molt, the young, which have acquired the typical scorpionlike appearance, come down off the mother's back. They remain close to her for a day or two and then scatter.

Scorpions live alone during most of their lives. They avoid each other, but when confronted, fight to the death, the victor usually devouring the victim. Growth is accompanied by molting, as in all arthropods. The old skin cracks around the carapace and is shed completely. The linings of the foregut, hindgut, and four pairs of book-lungs (situated on the ventral side of the third to sixth preabdominal segments) are also shed. The number of molts may vary, even in the same species; it is believed that *Palamnaeus longimanus* has eight and *Androctonus australis* seven.

Scorpion Poison.—Many observations on the effect of scorpion poison are unreliable for many reasons. Sources of error include a lack of knowledge of the physiological state of the victim, ignorance of the amount of poison absorbed, and the ratio of amount of poison to the total weight of the victim. Another serious source of error is that many observations refer simply to a "scorpion." There are more than 600 species of scorpions in the world, which vary greatly in degree of virulence and type of poison.

At least two general types of scorpion poison exist. One of these is local in effect and comparatively harmless to man; it is exemplified by the European *Euscorpius italicus*, the American *Centruroides vittatus*, *Vejovis spinigerus*, the formidable-looking *Hadrurus hirsutus* and *H. spadix* of Arizona and Utah, and the large *Centruroides margaritatus* of Central America. Some scorpions have reduced poison glands, and their venom has no effect. The other type is a dangerous neurotoxin that resembles the venom of some snakes; it is represented by the North American *Centruroides sculpturatus* and its close relative *Centruroides gertschi* and by the North African *Androctonus australis.*

The symptoms caused by scorpion poison of the less virulent type consist mostly in sudden sharp pain followed by numbness of the limb and local swelling. The symptoms pass within an hour or two. For a healthy non-allergenic adult man there is no more danger from this type of scorpion poison than there is from the sting of a wasp or a hornet. The neurotoxic venom has an affinity for the autonomic nervous system. The victim experiences a tightness in the throat, difficulty in speaking, restlessness, and slight involuntary twitching of muscles. Sneezing spasms may follow, accompanied by a flow of mucus from the nose and mouth. The rate of heart beat may be considerably increased. Convulsions

follow, and the extremities become bluish just before death occurs (anytime from 45 minutes to 10–12 hours after the onset of symptoms).

If administered early enough, antiscorpion serum, produced by injecting a ground preparation of scorpion terminal tail segments into horses, may reduce mortality to less than 3%.

The effect of the scorpion venom on different animals varies greatly. Hedgehogs, jerboas, and fennec foxes are nearly immune while guinea pigs and dogs are susceptible. Birds, frogs, and fishes are also sensitive.

The story that scorpions commit suicide by stinging themselves when surrounded by a ring of fire is based on misinterpretation of their behaviour and has long since been discredited. Certain scorpions possess a degree of immunity to their own venoms. This is true of *Palamnaeus scaber* (formerly *Scorpio afer*), according to older statements. Other species, *e.g.*, *Androctonus australis*, may be killed by injections of their own poison only when the dose is massive, nearly 200 times greater than the one necessary to kill a guinea pig.

Classification.—The Scorpiones are divided into six families, of which the Buthidae is the largest and most important. It has more than 600 species including *Buthus occitanus*, commonly found in the Mediterranean area and in France; *Androctonus australis*, the fat-tailed scorpion of North Africa; and the neotropical genera *Centruroides* and *Tityus*. The family Diplocentridae is found in the Palaearctic region, the island of Sokotra in the Gulf of Aden, and Mexico; the Scorpionidae, in Africa, Madagascar, Asia, and Australia; the Vejovidae, mainly in Asia and America; the Chactidae, in Asia, America, southern Europe, and the Mediterranean (one small species); the Bothriuridae, in Australia.

See ARACHNIDA.

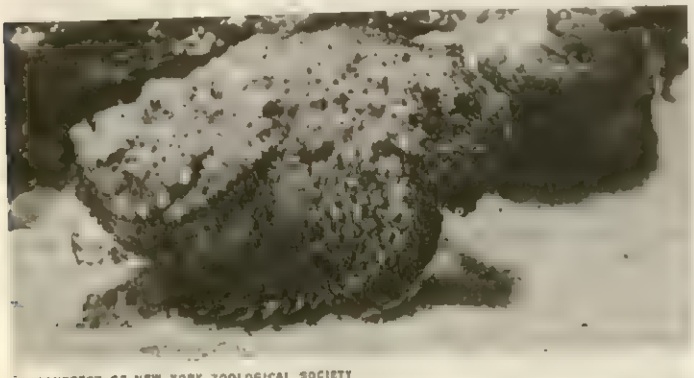
(C. J. Go.; M. L. G.)

SCORPION FISH, the name given to any of the spiny marine fishes of the family Scorpaenidae, characterized by a bony plate or stay across the cheek. The name is particularly used for many mostly small (a foot or less long), bottom species in the shore waters of all warm seas (*Scorpaena, Pterois*, etc.). These usually have mottled colours and are found on rough bottoms or among seaweed. In cooler, coastal waters of the North Pacific, there are larger (two or three feet long), freer-swimming, less spiny species (*Sebastodes*, etc.), commonly known as rockfish, and of greater market value. In the cold waters of the North Atlantic there is a bright red one, the rosefish, redfish, or ocean perch (*Sebastes marinus*), which is excellent eating. So far as known all members of the family are good to eat, but persons handling the tropical ones, especially, should use care, as wounds from their sharp spines may be very painful and cause swelling. The glands at the bases of the dorsal fin in the poison fish or stonefish (*Synanceja verrucosa*), of East Indian waters, can inflict severe wounds.



BY COURTESY OF NEW YORK ZOOLOGICAL SOCIETY

STONEFISH (SYNANCEJA VERRUCOSA), ONE OF THE MOST VENOMOUS OF THE SCORPION FISH

In the cool-water species, the eggs hatch within the body of the mother as a rule, broods of hundreds if not thousands of tiny fishes being spawned.

See also LION FISH; FISH: *Survey of the Bony Fishes.*
(J. T. N.; X.)

SCORPION FLY, the common name for insects of the family Panorpidae, order Mecoptera (*q.v.*), and by extension often applied to the order as a whole. The name refers to the fact that in male panorpids the abdomen terminates in a bulb-like segment which is held over the back, after the manner of a scorpion. In both sexes the chewing mouth parts are borne at the tip of a stout beak, the antennae are long and many-segmented, and there are two pairs of membranous, net-veined wings, which in many species are darkly spotted or banded. The largest genus, *Panorpa*, comprising about 170 species, is widely distributed in forested areas of the Northern Hemisphere. Adult scorpion flies, usually found on the wing in summer, feed on dead animals, especially insects, but the larvae are thought to be predaceous on minute soil animals. The immature stages of only a few species are known; the larvae resemble caterpillars, and pupation occurs in a cell in the soil.

ROSS E. HUTCHINS

A MALE SCORPION FLY (PANORPA) COMMON IN THE SOUTHERN UNITED STATES

Besides Panorpidae, the order includes the hanging flies, family Bittacidae, which hang by their forelegs and catch insect prey with their raptorial hind feet; and the tiny, blackish snow scorpion flies, family Boreidae, with greatly reduced wings.

Snow scorpion flies are occasionally seen walking over the surface of snow; both the adults and larvae are said to feed on mosses. The order is small, numbering about 350 known living species, but it is very widespread in distribution and is of great antiquity.

Scorpion flies are altogether harmless to man and serve a useful function in nature as scavengers.

SCOT, MICHAEL (d. *c.* 1235), Scottish scholar and mathematician whose translations from Arabic and Hebrew are a very important landmark in the reception of Aristotle in the Latin West, was famous in the Middle Ages as an astrologer and soon acquired a popular reputation as a wizard. There is no evidence as to where he obtained his master's degree, and he first appears at Toledo in 1217, where he finished translating the treatise of al-Bitrogi (Alpetragius) on the sphere. In 1220 he was in Bologna, and during the years 1224–27 may have been in papal service, as he is mentioned in several papal letters. A pluralist, he was promoted archbishop of Cashel in Ireland (May 1224), but declined the see a month later. In April 1227 Pope Gregory IX urged on the archbishop of Canterbury Michael's claims to benefices as one learned in Hebrew, Arabic, and Latin. Thereafter he was at the Sicilian court of the emperor Frederick II and was mentioned as recently dead in a poem written early in 1236.

His works are mainly undated, but those on natural philosophy seem to predominate in his earlier, Spanish period, and those on astrology in his later, Sicilian period. At Toledo, in addition to his translation of al-Bitrogi, Michael translated Aristotle's *Historia animalium* from Hebrew or Arabic. He also translated, perhaps at this time, Aristotle's *De caelo*, and he was probably responsible for the translations of the *De anima* and the commentary by Averroës which is found in the same manuscripts. There is no evidence that Scot translated Aristotle's *Physics, Metaphysics*, or *Ethics*.

In the Sicilian period he wrote three treatises on astrology: the *Liber introductorius*, a long popular work on astronomy and astrology, sometimes citing the author's own experiments; the *Liber particularis*, much shorter, dealing mainly with the reckoning of time, the calendar, and meteorology, ending with a series of questions on the relationship of earth, infinity, and heaven, posed by Frederick II and ineptly answered by Michael; and the *Physionomia*, designed to help the emperor in his judgments of men, containing a treatise on generation and an account of prognostication from dreams, complexions, and the different parts of the body. His work exhibits the worst failings of contemporary learning: prolixity, incoherence, and uncritical credulity.

Michael dabbled in alchemy, and by the Renaissance several alchemical works were ascribed to him; however, his authorship of none of these is proven. He appears in the *Inferno* of Dante (xx) among the magicians and soothsayers and has the same role in Boccaccio. He also made medical observations, but the "pills of Master Michael Scot" have nothing to do with him.

BIBLIOGRAPHY.—C. H. Haskins, *Studies in the History of Medieval Science* (1924); L. Thorndike, *History of Magic and Experimental Science*, vol. ii (1923); *Michael Scot* (1965). (A. A. M. D.)

SCOTLAND, the most northerly of the three countries of Great Britain. It is a generally cool, hilly, and in the west a wet country which stretches from the Solway Firth and the English border to the Pentland Firth in the north, with the Orkney Islands, Fair Isle, and Shetland Islands beyond, and from the North Sea in the east to the Atlantic islands of the Hebrides and St. Kilda in the west. Area 30,412 sq.mi. (78,768 sq.km.). Pop. (1961) 5,179,344. The capital is Edinburgh.

The mainland is 274 mi. (441 km.) from Cape Wrath, Sutherland, to the Mull of Galloway and 154 mi. (248 km.) from Buchan Ness to Applecross in western Ross; but it is only 26 mi. (42 km.) wide between the estuaries of Dornoch Firth and Loch Broom and 30 mi. (48 km.) between the Firths of Forth and Clyde. The indented coastline of about 2,300 mi. (3,700 km.) causes few areas to be over 40 mi. (64 km.) from the sea but in places obstructs land routes or causes expensive bridging as at the Firths of Forth and Tay. Scotland is separated from England by the Solway Firth, the Sark, Scotsdyke (an old embankment between Sark and Esk), the Esk (for 1 mi.), the Liddel, the Kershope, the Cheviot Hills, the Tweed, and a small area known as the "liberties" of Berwick. The name Scotland originated in the 11th century when the name Scotia was given to a southwestern tract settled by the tribe of Scots who had migrated from Ireland, to which land the name Scotia had previously been applied. The older name Caledonia long remained in use poetically. (A. T. A. L.)

This article contains the following sections and subsections:

For subjects concerned with the United Kingdom as a whole (*e.g.*, constitution, legislature, defense, finance and trade) *see* GREAT BRITAIN AND NORTHERN IRELAND, UNITED KINGDOM OF.

I. PHYSICAL GEOGRAPHY

1. Geology.—Scotland lies on the course of a southwesterly trending mountain chain of pre-Devonian Age, which stretches from Scandinavia to Ireland and was called Caledonian by Eduard Suess. In Scotland the northwestern front of this chain is marked by the Moine Thrust outcropping in the Northwest Highlands and extending from Durness to Skye. Its latest manifestation is the corrugation of Ordovician and Silurian in the Southern Uplands, where Charles Lapworth demonstrated the value of graptolites (*q.v.*) in determining the succession of strata.

Precambrian Below the Moine Thrust.—Precambrian rocks which occur beneath the Moine Thrust have been widely exposed in the islands and coastal belt of the Northwest Highlands. They consist of the Lewisian complex, predominantly igneous and almost wholly metamorphic, and the unconformably overlying Torridonian sediments, almost everywhere nonmetamorphic.

FIG. 1.—MAJOR PHYSICAL FEATURES, CITIES, AND TOWNS OF SCOTLAND

The igneous rocks of the Lewisian range from ultrabasic (rich in olivine and calcic feldspar) to ultra-acid (containing a high percentage of silica and yielding quartz); many have suffered in varying degree from two metamorphisms separated by a long time interval. In the Assynt district the following history has been deciphered: (1) formation of a "fundamental complex" of metamorphic igneous rocks; (2) cooling of this complex; (3) intrusion, with chilled margins, of a great suite of west-northwest basic dikes (named after the hamlet Scourie); (4) reheating accompanied by widespread, though not universal, differential movement and intrusion resulting in a second metamorphism (named after Loch Laxford). In a large proportion of Lewisian outcrops Scourie dikes are not distinguishable with certainty. This is due in part to Laxfordian metamorphism having obscured the contrast between dikes and country rock; but it may also be due in part to large-scale incorporation in the Lewisian complex of rocks later than the Scourie dikes. Certain considerable outcrops of Lewisian sediments, including magnesian marbles and graphite schists, are not cut by Scourie dikes. Such sediments in Coll and Tiree carry massive intercalations of igneous gneisses almost certainly later than themselves. After the Laxfordian high temperatures had passed away, sudden movements locally developed frictional heat sufficient to cause incipient fusion on a very small scale. This, followed by a quick cooling, produced crush rocks (*see* BRECCIA) with flinty appearance. An unusually prominent development of "flinty" crush rock follows an east-southeasterly inclined shear zone along the east coast of the Outer Hebrides.

The uncomformable Torridonian sediments probably accumulated under continental conditions. From Islay to Skye, they start with Lower Torridonian basal conglomerates (*q.v.*), grits rich in the mineral epidote (*q.v.*), grey sandstones, flags, and grey and black shales (7,000 ft. [2,130 m.]). Farther north, Middle Torridonian arkose, a type of coarse sandstone (6,000–8,000 ft. [1,830–2,440 m.]), with scattered breccias, rests among and covers over "fossil hills" of Lewisian gneiss, which are sometimes more than 2,000 ft. in individual height. Upper Torridonian sandstones, flags, and shales attain 4,500 ft.

Early Paleozoic Below the Moine Thrust.—A very regular marine succession of Durness sediments (Lower Cambrian extending into Lower Ordovician) lies with angular unconformity on gently folded Torridonian and Lewisian complex. The lithology and fauna are: basal quartzite (320 ft.); quartzite with vertical worm casts, sand-filled tubes formed by burrowing worms (*Scolithus linearis*) (270 ft.); dolomitic shales, mudstones, and dolomites, with the trilobite (*q.v.*) *Olenellus* (50 ft.); grit, with *Salterella* and *Olenellus* (30 ft.); limestones and dolomites, some fossiliferous (1,500 ft.). At Assynt plutonic (possibly early Devonian) intrusions of alkali-syenite, borolanite, etc., accompanied by sills, cut these sediments. Contact effects include dedolomitization (limestone is converted due to interaction between dolomite and igneous rock).

Moine Thrust Zone.—The Moine Thrust, traceable from Whiten Head near Durness to Skye, is of early Paleozoic date. As a result of this thrust crystalline sedimentary schists are found overlying the Cambro-Ordovician and Torridonian nonmetamorphics. The alkali-syenites of Assynt underlie the thrust; but some associated sills are intruded into the overlying schists. The suite has suffered much of the movement registered in the thrust zone, but perhaps not all. An alkali-syenite at Ben Loyal may be a late member.

Near Durness a thrust outlier (klippe) of the Moine Thrust mass (nappe) is downfaulted 10 mi. in advance of the main out-

crop. In Assynt and Glencoul, subsidiary thrusts carry 1,500-ft. slices of Lewisian for miles over Cambrian. Spectacular inversion occurs at Loch Alsh, where, as in Colonsay, disturbed Torridonian develops minute biotites (*see* BIOTITE) of Moine Thrust Age. *Schuppen* structure (*i.e.*, slices overthrust one upon another) and mylonization (*see* MYLONITE) are among the structures diagrammatically exposed at many localities.

Pre-Devonian of the Highlands Between the Moine Thrust and the Great Glen.—The sedimentary schists above the Moine Thrust extend southeast to the Caledonian Canal along the Great Glen. They are mostly quartzofelspathic or micaceous and grouped as Moine schists. With them, at Glenelg and elsewhere, are several minor outcrops of Lewisian-like igneous and sedimentary types. These are commonly interpreted as inliers of Lewisian and as interfolded and remetamorphosed with the Moines which are supposed to be unconformable. Inchbae porphyritic granite (*see* PORPHYRY), now gneissose, was intruded into the Moines before these last had suffered regional metamorphism, since adjacent indurated hornfels (*q.v.*) retains minutiae of sedimentary structures, such as grains, ripple marks (*q.v.*), and sun cracks. Garnets are widely developed in the Moine schists; and, some distance east of the Moine Thrust, sillimanite (*q.v.*) is commonly associated with granitic injection. Underlying the Moine Thrust at Tarskavaig in Skye, there is a thrust mass, the rocks of which are variously interpreted as Moines or Torridonian. Some geologists think all Moines are metamorphosed Torridonian; others regard Moine metamorphism as pre-Torridonian.

Great Glen Fault.—The Great Glen is eroded along a belt of intense shattering connected with the Great Glen fault. This fault according to good, though inconclusive, evidence is a sinistral wrench fault (*see* FAULT) with horizontal displacement of 65 mi. It appears, for instance, to shift the northern part of the Foyers granite (Loch Ness) southwestward to the Strontian district.

Pre-Devonian of the Highlands Southeast of the Great Glen Fault.—The Moine Series crosses the Great Glen fault, but the northeast, east, and southwest part of the Grampian Highlands consists of Dalradian schists, probably of post-Moine age. In the Dalradian (*see* PRECAMBRIAN TIME: *Scotland*) quartzites, limestones, and graphitic schists are characteristic members; the Schiehallion boulder bed may be glacial; pillow lavas occur at Loch Awe; basic intrusions are widespread. Current and graded bedding (the former also in the Moines) help to determine the stratigraphical order. The Dalradians overlie Moines, pitching off them toward Loch Awe and the county of Banff. Large-scale recumbent folds with fold faults (slides), the whole refolded, are typically shown at Ballachulish and elsewhere.

Zonal mapping of regional metamorphism was first carried out in the Dalradian belt. The grade varies from roofing slate to sillimanite-gneiss and is low at Loch Awe, in Banff, and along the Highland border. In the sillimanite zone, granitic permeation is characteristic. Recent research has concentrated on the study of minor folds and mineral orientation.

Middle Cambrian limestone (near Callander) and Upper Cambrian to Ordovician pillow lavas, radiolarian (*see* PROTOZOA: *Classification and Survey: Radiolarida*) cherts, and serpentine (probably as folded sheet) with fossiliferous shales outcrop discontinuously along the Highland boundary fault. At Stonehaven they are unconformably overlain by Downtonian (a division within the Devonian system, *q.v.*) sandstones with mudstones, tuffs (rocks formed by induration of volcanic ash or dust), and conglomerates (2,760 ft.), which yield fish and the fossil *Dictyocaris*.

Highland Boundary Fault.—From Stonehaven to beyond Loch Lomond runs the Highland boundary fault. It has generally functioned as a broken monocline (with complications) throwing down toward the Midland Valley (termed mid-Lowlands hereinafter). It was active during much of Old Red Sandstone times and probably earlier. In post-Carboniferous times, at Loch Lomond, it threw back, down toward the Highlands.

Pre-Devonian of the Mid-Lowlands.—The Stonehaven-Downtonian strata, strongly tilted, are followed conformably by Lower Old Red Sandstone. Similar conformity holds at Lesmahagow, where gentle anticlines expose the following succession: Graywacke (*q.v.*) and shale possibly of Wenlock age (1,300 ft.); Ludlow mudstone, graywacke, and shale (1,480 ft.); Downtonian yellow, red, and chocolate sandstone with a quartzite conglomerate and some mudstone (2,700 ft.). Pentland inliers again show a Wenlock to Downtonian succession, but here Lower Old Red Sandstone follows with strong unconformity. The Wenlock-Ludlow (*see* SILURIAN SYSTEM) rocks of both districts have yielded many brachiopods (*see* BRACHIOPODA) and mollusks, especially in the Pentland Hills; also scorpion, phyllocarids (*see* MALACOSTRACA: *Phyllocarida*), eurypterids (*see* EURYPTERIDA), and fish. The three last reappear in the Downtonian. In the Girvan district, Arenig to Wenlock emerge from beneath unconformable Lower Old Red Sandstone considerably northwest of the Southern Uplands fault.

Southern Uplands Fault.—The mid-Lowlands are bounded to the southeast by the great Southern Uplands fault. In the southwest this crosses the mouth of Loch Ryan and continues northeast till, south of Edinburgh, it turns abruptly southward. Thereafter, resuming its northeast trend, it reaches the coast just south of Dunbar. Ordovician rocks of the Southern Uplands outcrop almost continuously on its southeast side, brought against successively: for the first 30 mi., in the southwest, Girvan outcrops of Ordovician lying to the northwest; for the next 60 mi., Lower Old Red Sandstone; and for 30 mi. to the North Sea, Carboniferous and Upper Old Red Sandstone. The Sanquhar coalfield has been preserved by late backthrow down toward the Southern Uplands.

Ordovician and Silurian of the Southern Uplands and Girvan.—Closely packed isoclinal folding and rapid cross-strike change of both facies (distinct kinds of rock or biologic associations) and thickness are characteristic. The Ordovician commences with Arenig pillow lavas, probably continuing into the Llandeilo group, capped by Llandeilo radiolarian cherts (70 ft.)—the term Llandeilo is used in Lapworth's sense. Near Girvan 1,500 ft. of Arenig-Llandeilo volcanic rocks are associated with serpentine, gabbro, and granite; the whole was exposed to erosion before the deposition of conglomeratic Upper Llandeilo (830 ft., including 60 ft. interbedded fossiliferous Stinchar limestone). Southeast of Stinchar Valley, Upper Llandeilo becomes conformable to the volcanic series, and consists of mudstones and grits (500 ft.) and conglomerate (500 ft.). Farther southeast it passes to grit and graywacke (1,000 ft.) and then, near Moffat, to 20 ft. of graptolitic shale (Glenkiln). The Caradoc (including Ashgillian) at Girvan is mostly mudstones, grits, flags, and shales (2,800 ft.) with interbedded shelly and graptolitic faunas. Near Moffat this reduces to 100 ft. of graptolite shale and barren mudstone (Hart Fell). Acid lavas occur at Wrae in Tweeddale.

A general paleontological break introduces the Silurian, although without upheaval at Moffat. The Llandovery series (*see* SILURIAN SYSTEM) at Girvan consists of conglomerates, grits, flags, shales, and thin limestones (1,050 ft.) with interbedded shelly and graptolitic faunas. Near Moffat there are only 100 ft. of graptolite shale (Birkhill). The Tarannon, however, both at Girvan (2,100 ft.) and at Moffat (3,000–4,000 ft.), consists of grits, flags, and shales with occasional graptolitic intercalations. Wenlock is doubtfully represented near Girvan by conglomerates, grits, flags, and shales (500 ft.) with minor graptolitic and shelly layers. Near the English borders Wenlock conglomerates, grits, graywackes, shales, and mudstones (1,000 to 1,500 ft.) contain several graptolitic bands with occasional eurypterids. Shelly layers also occur. In the same district Ludlow mudstones with limestone nodules and grits (500 to 750 ft.) yield shells.

Ordovician and Silurian conglomerates usually contain material derived from Arenig lavas suffering erosion north of the Southern Uplands. Quartzite appears as pebbles in the Caradoc and mica-schist in the Llandovery. The graywackes frequently show graded bedding. Undated post-Silurian mineral veins occur at Leadhills. (For an explanation of the terms Caradoc, Llandeilo, and Arenig, *see* ORDOVICIAN SYSTEM.)

Devonian.—All the Scottish Devonian is continental Old Red Sandstone. In basal exposures, except at Stonehaven and Lesmahagow, it follows on older rocks with striking unconformity. In depth, however, under the mid-Lowlands, conformity with Downtonian may perhaps be the rule. Three divisions are recognized

with distinct faunas and floras. Fish have furnished the majority of determinable fossils. The Lower Old Red Sandstone is most fully preserved in the mid-Lowlands (19,000 ft., including lavas, in the county of Kincardine). Dull purplish brown sandstone is widespread, covered in Strathmore by red sandstones and marls. Mid-Lowland conglomerates attain great prominence toward the Highlands and Southern Uplands. Subalkali volcanic rocks, including basalt, andesite, and rhyolite (*qq.v.*), occupy a roughly central position in the Lowland succession (6,500 ft. in the Ochil Hills and well exposed also from the Pentland Hills to Ayrshire). In the Highlands (Oban, Glencoe, Ben Nevis) and also at Cheviot, lavas greatly exceed sediment; Stonehaven conglomerates show that early Highland volcanoes of the suite started in Downtonian times. Glencoe and Ben Nevis are famous for their cauldron subsidences. At both these localities granites and quartz diorites (*see* DIORITE) with northeasterly dike swarms are associated with the cauldrons. Granites cutting Lower Old Red Sandstone also occur at Distinkhorn (Ayr) and Cheviot. Others penetrate folded Silurian (Southern Uplands). Many undated Highland granites are probably of Lower Old Red Sandstone Age; but granite pebbles are well known in Lower Old Red Sandstone conglomerates (Glencoe, Stonehaven).

Middle Old Red Sandstone is widely developed in northeast Scotland (18,000 ft. in Caithness), extending to Orkney and the Moray Firth. It largely consists of flags, often bituminous, calcareous, ripple-marked, and sun-cracked. The Rhynie chert with wonderfully preserved plants is generally referred to this formation.

Upper Old Red Sandstone (some thousands of feet thick) is found in the mid-Lowlands and to a limited extent in northeast Scotland; it is everywhere, except perhaps in Shetland, unconformable to its predecessors. Red sandstones with some wind-rounded grains are common in its earlier parts; while paler sandstones with cornstones (concretions of impure sandy limestones) occur toward the conformable base of the Carboniferous.

Carboniferous.—The Scottish Carboniferous, marine, estuarine, and terrestrial, is typically developed in the mid-Lowlands and along the English border. These two areas of deposition were always connected across the eastern end of the Southern Uplands; but farther west (near Sanquhar) Upper Carboniferous rests on Ordovician and Silurian. In the Highlands, Carboniferous (though represented at Campbeltown, Bridge of Awe, and Morven) is scarcely known. In the mid-Lowlands and on the borders it follows Upper Old Red Sandstone conformably, though with a different set of fishes. Subdivisions in Edinburgh district are: Calciferous Sandstone series, including Cementstone group (1,000 ft.) and Oil Shale group (3,000 ft.); Scottish Carboniferous Limestone series, including Lower Limestone group (700 ft.), Limestone Coal group (1,050 ft.), and Upper Limestone group (1,050 ft.); Scottish Millstone Grit (800 ft.); Productive Coal Measures (1,500 ft.); Barren Red Coal Measures (in Ayr, 1,500 ft.). On the basis of zonal fossils the naming of these divisions has recently been revised to facilitate comparison with the standard English succession: the Calciferous Sandstone and Lower Limestone grouped together correspond with the English Carboniferous Limestone; the Limestone Coal and Upper Limestone groups equate with much of the English Millstone Grit; while the Scottish Millstone Grit is renamed Passage group, and belongs partly to the English Millstone Grit, partly to the Coal Measures. It is widely thought that the conjunction of Millstone Grit and Coal Measures in the Passage group is unconformable, and that this accounts for a plant and estuarine fish break recognized by R. Kidston and R. H. Traquair. The base of the Barren Red Coal Measures is defined for stratigraphical purposes at the top of the Skipsey Marine Band. Actually the reddening does not allow stratigraphy at all closely. It has been determined by subterranean penetration of a desert climate during New Red Sandstone times, which led to widespread oxidation of iron carbonate and sulfide, and, in Ayrshire, to local replacement of coal by calcium and magnesium carbonates.

The oil shale and two coal-bearing groups (with clayband and blackband ironstones) are economically valuable, though oil shale is little worked today. Marine limestones are scarcely represented except in the Lower and Upper Limestone groups (near Edinburgh eight beds reach the quite exceptional total of 230 ft.). A well-known 40-ft. freshwater limestone (Burdiehouse) occurs in the Oil Shale group. High quality fireclays are worked in the Passage group.

Rapid variations of thickness are characteristic, as on the two sides of the Kerse Loch fault near Patna in Ayr. Change of facies is exemplified by restriction of workable oil shale to West Lothian and its borders. Vulcanicity was common till the close of the Millstone Grit and has recently been found to extend into the Coal Measures under the Firth of Forth. Special volcanic activity reigned about the end of the formation of the Cementstone group (Clyde Plateau, Arthur's Seat, Garleton Hills). Products are distinctly, but not strongly, alkaline. They include essexitic basalts (of granular, intrusive type), mugearites, trachytes (*see* TRACHYTE), and phonolites (*see* PHONOLITE). Contemporaneous weathering of Millstone Grit basalts has given valuable bauxitic clay (Ayr). Volcanic necks filled with basaltic agglomerate are well displayed (Arthur's Seat, Campsie Fells). Some scarcely transgressive, much faulted sills of olivine-dolerite and teschenite (*see* THERALITE) may be Carboniferous (West Lothian).

Permo-Carboniferous.—Approximately at the close of Carboniferous times there was considerable folding and faulting, which developed, among other structures, many east-west faults. The movements were accompanied by intrusion of quartz-dolerite magma, affecting, more particularly, an east-west belt (Highland and Lowland) with Dundee near its northern limit and Glasgow near its southern. In most of this belt long, broad, isolated east-west quartz-dolerite dikes are characteristic; but about the Forth (Fife, Stirling, Kilsyth, Airdrie, Linlithgow, Queensferry) the dikes are associated with, or give place to, sills of identical composition. In the Lomond Hills of Fife one of these sills is pierced by Permian necks. This feature is continued over the Scottish border in Northumberland and Durham where the dike-sill association is found again east of the Eden Valley (Great Whin Sill) and is unconformably overlain by Permian sediments.

Permian.—From the Solway northwestward a train of Permian outcrops reaches intermittently across the Southern Uplands (overlying various formations from Silurian to Productive Coal Measures) and mid-Lowlands (overlying Barren Red Coal Measures) to Arran. In Ayr the Permian succession consists of lavas and tuffs (basalt and nepheline-basalt, 500 ft.) succeeded by brick-red desert sandstone (1,500 ft.). The volcanic period produced many necks there, and those in Fife are probably of the same period. Several nepheline-essexite sills (kylite) in Ayr clearly cut faulted Coal Measures and are certainly Permian. Many of the teschenite sills of Ayrshire and elsewhere in the mid-Lowlands are also, with high probability, of this date. So too are monchiquite dikes (*see* LAMPROPHYRE), common in the Ayr coalfield. Farther north, from Colonsay to Orkney, a camptonite-monchiquite suite of dikes has given rise to much discussion. They sometimes follow approximately the local direction of Tertiary dike-intrusion. A dike that may be a nontypical representative is covered unconformably by Trias in Morven; while a well-characterized example in Colonsay has given a helium figure which also supports ascription to the Permian. The alkali products of Permian igneous activity in Scotland seem to go naturally with the Exeter volcanics in England and the famous Oslo association in Norway.

At Elgin an outlier of reptiliferous sandstone (*Gordonia* beds of Cuttie's Hillock) is of marked desert character and is referred to uppermost Permian or basal Trias.

Trias.—In Arran 2,000 ft. of Permian, mostly brick-red desert sandstone and breccia, underlies 1,000 ft. of Triassic interbedded sandstone and marl with occasional nodular limestone. A mass fallen into a Tertiary volcanic neck includes the Lamellibranchia *Pteria contorta* shales (Rhaetic).

The base of the Mesozoics from Mull northward consists of Trias conglomerates and sandstones with concretionary cornstones. Red coloration is often subordinate. In western Mull 200 ft. of these rocks underlie 40 ft. Rhaetic with *Pteria contorta*. Elsewhere Rhaetic is only doubtfully distinguishable. Some of the Elgin sandstones (Lossiemouth) have yielded mid-Triassic reptiles.

Jurassic.—Low-lying outcrops of Jurassic, conformable to Trias, are preserved on the west and east coasts of the Highlands. On the west, where a cover of Tertiary lavas has furnished additional protection, a typical area, richly fossiliferous, is Skye and Raasay: Lower Lias (Broadford Beds, with limestones rich in the oyster *Gryphaea*, 340 ft.; Pabba Shales, 700 ft.); Middle Lias (Scalpa Sandstone, 240 ft.); Upper Lias (shales, 80 ft.; thinner with 8 ft. ironstone in Raasay); Inferior Oolite (mainly sandstone, 780 ft.); Bathonian Great Estuarine series (bituminous shales with thin shelly limestones, 600 ft.); Cornbrash (limestone with comminuted shells, only in Raasay, 20 ft.); Callovian, restricted (sandstone remnant in Skye); Oxfordian (shales, 120 ft. in Skye); Corallian (calcareous grits and shales, 140 ft. in Skye); Kimmeridgian (shales, 40 ft. in Skye).

At Brora on the east coast are found: Lower Lias (shales with thin coals, 80 ft.); gap in the series due to fault; Great Estuarine series (more than 80 ft. of shale, sandstone, etc., with 3 ft. Brora coal at top); Callovian, restricted (marine limestone, 5 ft.); Lower Oxfordian (shales, 275 ft.); Upper Oxfordian (gritty sandstone, 170 ft.); Corallian (limestone, 20 ft.; sandstone and shales, 200 ft.); Kimmeridgian (shales and boulder beds, 1,500 ft.). The boulders of the boulder beds consist of Middle Old Red Sandstone. Many are big; one measures 150 × 90 × 30 ft. They have fallen from an intermittently renewed, submarine fault scarp and are mixed with Kimmeridgian corals and shells. The cumulative throw of the fault exceeds 2,000 ft. In Skye another 2,000-ft. post-Corallian fault can be shown to have been planed down by erosion before Upper Cretaceous times. In Mull and on the Moray Firth the Great Glen fault seems to have stirred in Kimmeridgian times.

Cretaceous.—Transgressive Upper Cretaceous is known: *in situ* (Skye, Scalpa, Raasay, Eigg, Mull, Morven); as a block fallen down a Tertiary crater (Arran); as *remanié* flints (Aberdeen); and as glacial erratics (Leavad, Caithness). The Morven succession is: Cenomanian greensand (45 ft.); white sandstone, worked for optical glass (35 ft.); silicified chalk with the zonal cephalopod *Belemnitella mucronata* (5 ft.) (*see* CEPHALOPODA). The white sandstone consists of desert sand blown on to the Scottish shore of the Franco-Britto-Russian Chalk Sea. Desert conditions presumably reduced river pollution to a minimum. In Morven, Cretaceous is still preserved 1,600 ft. above present sea level.

Tertiary, Mainly Igneous.—The Cretaceous chalk was upraised, weathered, and silicified, and its crannies filled with desert sand (Mull). Subsequent conglomerate, lateritically weathered ash, and leaf beds among lavas imply a change to moist climate and volcanic eruptions. The plants have suggested to some early Eocene, to others Oligocene to Miocene. Subaerial basalt lavas characterize Skye, Eigg, Mull, and Morven (also Antrim). Exceptionally these lavas are columnar (Staffa). The basalt succession in Mull is olivine-rich flows (3,000 ft.) followed by olivine-poor flows (3,000 ft.). The Sgur of Eigg pitchstone seems to be an acid lava that filled a valley, the sides of which, consisting of basalt, have since been mostly eroded away. Great plutonic centres occur at St. Kilda, Skye, Rum, Mull, Ardnamurchan, and Arran. Some think that most of the lavas, still preserved, were fed from these centres. A Kilauean sink, repeatedly renewed in central Mull, was often filled by a crater lake, and lavas flowing into it developed pillow structure. Vent agglomerates are abundant in Skye, Rum, Mull, Ardnamurchan, and Arran.

The Skye plutonic centre is well known for its gabbro (*q.v.*) to granophyre (composed mainly or wholly of micropegmatite; *q.v.*) succession; Rum for its banded peridotites (*see* PERIDOTITE); Mull and Ardnamurchan for their ring-dikes. In Mull the plutonic succession is complex and begins with granophyre; in Ardnamurchan it is essentially gabbroidal. In Rum a ring-fault is associated with central and peripheral upheaval; the main recent discovery in Rum is that its granophyre (forming Mt. Orval) is earlier than its basalt lavas; Arran is specially noteworthy for the doming of its granite's roof. Arcuate peripheral folding is a feature of Mull and Skye. Cone-sheet complexes are extensively developed in Skye, Mull, and Ardnamurchan. The Skye, Rum, Mull, and Arran centres have crowded dike swarms. The general dike direction is northwest.

KENNETH SCOWEN

LOCH CAIRNBAWN, NEAR QUINAG, IN SUTHERLAND, NORTHERN SCOTLAND

Some believe that most of the Hebridean lavas were fed from dikes (fissure eruptions). It is certain, however, that the great centres were established before the dike swarms, since they locate the latter. It is also certain that most of the dikes are later than any lavas spared by erosion.

West Highland scenery has been shaped entirely since the Tertiary eruptions. The magnificent mountain and valley forms of Skye are cut in Tertiary plutonics.

Possible Pliocene gravels occur near Turriff, Fyvie, and in central Buchan, all in Aberdeenshire.

Pleistocene and Recent.—During the Pleistocene glaciation, Scotland functioned as a complex centre of dispersal in the great north European ice sheet. Scandinavian ice currents freely invaded England. Some districts were crossed by ice that traversed the bed of the sea bringing in shells and, in Caithness, Mesozoic erratics. Glacial erosion is often pronounced. Crag and tail is developed to perfection in Edinburgh and elsewhere. Rock basins are numerous in the Highlands (*e.g.*, Loch Coruisk). Some of the consequences of glacial deposition are: in the west Highlands, hummocky moraines; east Highlands, fluvioglacial gravel; mid-Lowlands, boulder clay, either flat or in drumlins, and gravel kames. In Glen Roy glacially dammed lakes are recorded by conspicuous strand lines; and throughout most of eastern Scotland glacially diverted rivers can be traced by channels now left dry.

Raised beaches up to about 100 ft. occur around Scotland but not in the Outer Hebrides, Orkneys, and Shetlands. The higher beaches are of late glacial age and were locally interfered with by glacial readvance (Loch Lomond and Mull). The most marked raised beach form is that known as the early Neolithic which varies in height from 0–35 ft. but is commonly found at 30 ft. and exhibits a temperate fauna. It rests in places on a peat or forest bed that continues below sea level. Traces of early man are found in this type of raised beach. (E. B. B.)

2. Relief and Drainage.—Scotland is often divided into three main landform regions: (1) the Highlands and islands, with the east coast Lowlands; (2) the mid-Lowlands, which include hill masses roughly between the boundary fault lines Stonehaven-Helensburgh-Bute and Dunbar-Girvan (the latter presents a much less clear boundary topographically than the former); (3) the Southern Uplands including the dales and fringing Lowlands, notably those fronting the Solway Firth and in lower Tweeddale. In each of these three divisions are marked distinctions of scenery between west and east. Yet throughout the landforms are dominated by a series of plateau surfaces dissected by erosion, especially in the west and markedly on the higher surfaces. In the mid-Lowlands and around the Southern Uplands, the plateaus rise in three main steps to summit planes of 1,500–2,000 ft. (450–600 m.) in the hills. Somewhat comparable steps are seen in the northeast and the Moray Firth Lowlands, but in the Highlands the sum-

mit planes are commonly 2,500–3,500 ft. (760–1,060 m.) and the monadnocks of Ben Nevis and the Cairngorms rise above this level to exceed 4,000 ft., while lower Highland plateaus and some valley floors may correspond with the higher surfaces of central and southern Scotland. D. L. Linton suggests that by the Cretaceous Period a low monotonous peneplain had developed cutting across various older rocks, upon which a thin cover of chalk was deposited; Tertiary uplift connected with the Alpine orogenesis raised the rocks, especially in the west and between Ben Nevis and the Cairngorms where they are higher. The main original west-east drainage pattern developed at first on the chalk, from which it was superimposed onto the diverse rocks below. There was much subsequent adjustment to underlying structure and further changes in the pattern caused by the Quaternary glaciation. The thin chalk being stripped off, the surface beneath was exposed at heights varying from 1,500 ft. in the extreme northeast to 3,500 ft. in much of the west and with a maximum of 4,300–4,400 ft. from Ben Nevis to the Cairngorms, the evidence in the present landscape being residual summits in watershed areas. Much more work is needed to determine the possible relationships and origins of the lower surfaces already noted. The Minch and the Irish Sea may have been formed by rift valley downfaulting, associated with the Tertiary basalts of Skye, Mull, and Antrim. The short, vigorous west-flowing streams and higher precipitation in the west have led to greater dissection of the erosion surfaces there. The main centres of Quaternary ice dispersion were in a westerly belt from Loch Torridon to Loch Lomond and again in Galloway, where the landscape is composed of spectacular isolated peaks, deeper corries, and wilder valleys than farther east. From this belt glaciers fanned out, altering valleys, sometimes breaching watersheds and changing the preglacial drainage pattern, gouging out many ribbon lakes, straightening and deepening the eastern glens, and depositing great sheets of boulder clay, sometimes in drumlins, on the Lowlands of the east, the mid-Lowlands, and lower Tweeddale. During the glacial phases of the Pleistocene Period the weight of the ice caused depression of the land. During the warm interglacial phases and in the post-Quaternary Period coastal submergence followed the ice melt as sea level rose; simultaneously isostatic readjustment occurred as the weight of the ice diminished on the land surface. The resulting slight uplifts produced raised beaches at several levels up to 100 ft. above mean sea level, some covering marine-cut rock benches probably formed during interglacial periods. Melt water from ice flattened many valley bottoms and temporary lake beds, carved new river channels which still form gorges, and left many dry channels and large spreads of sand and gravel. Since glacial times, normal erosion has continued to modify the landscape; while sea erosion modifies the coast lines, undercutting headlands, particularly where exposed to long-fetch Atlantic waves as around Cape Wrath and in Orkney, and builds beaches, dunes, and locally cuspate headlands.

Of the postulated original drainage pattern, the west-flowing rivers, though remaining relatively short, have enlarged their catchments eastward of the main western line of peaks. Glacial watershed breaching has also been important in forming through valleys and low passes. The postulated main east-flowing rivers now form a river network showing much adjustment to underlying structure, in places aligned northeast to southwest with the Caledonian trend, *e.g.*, the River Spey, and in places at right angles to the Caledonian trend. Similar adjustments to structure may be seen in the west coast river valleys and fjords. Glaciation has greatly influenced the evolution of the present drainage pattern. Glacial breaching of watersheds has altered the course of many a preglacial river and in some cases facilitated river capture. For example, it is postulated that because of glacial breaching of the watershed the postglacial Avon River captured the waters of the upper Don.

3. Climate.—Scotland naturally shares with the rest of the British Isles a cool west maritime climate, largely dominated by the repeated passage of easterly moving depressions and occlusions of the circumpolar front. The western fringe of the mainland and the Hebrides have mild though wet and windy winters with January mean temperatures of 40°–42° F (4.4°–5.5° C) and subtropical plants grow in sheltered gardens as far north as 58° N. The frost-free period in the west is about a month longer than in the east. The east coastal belt is subject to rather more continental influences and is colder (January means about 39° F; 3.8° C) and drier in the winter though these months are the wettest of the year. It is still colder inland, by a degree or two, and more on high ground or in frost hollows, and there is more than 30 days' snow cover above 2,000 ft. (610 m.). Spring and early summer are often relatively dry though rather cool (April means 43°–45° F; 6.1°–7.2° C). From midsummer to late summer conditions are often fairly cool, wet, and cloudy with monthly means 54°–55° F (12.2°–12.7° C) in the extreme north and 58°–59° F (14.4°–15.0° C) in the centre and south. The sunniest areas, in the east, receive 4½ hr. of sunshine per day in August, compared with 6–6½ in June. In the western coastal tract and in the western half of the mid-Lowlands mean annual rainfalls are about 40–50 in. (1,000–1,270 mm.); in hilly areas over 60 in.; in mountainous western tracts over 100 in. (2,540 mm.); and in the eastern Highlands 50–60 in. Mean annual rainfall is lower in the east coastal areas and the eastern half of the mid-Lowlands (30–35 in.), where they are not exposed to the strong rain-bearing westerlies from the Atlantic. The extreme east is remarkably dry with under 25 in. on the coast itself where spring droughts sometimes occur.

River flow fluctuates seasonally though there is rain all year; average winter flow with high precipitation and low evaporation is commonly 15 times that of summer, which comes after the drier spring and early summer and in conditions of high evaporation. A winter flood is often 300 times the low stage of a summer drought, though some of the most destructive floods have occurred after exceptional summer storms following a wet spell. This seasonal fluctuation raises problems for hydroelectric generation and also for water engineers, though Scotland in general has ample water supplies. The large area which receives more than 50 in. of rain in over 70% of years includes much of the hill country within the mid-Lowlands, and of the Southern Uplands and the west Highlands. Useful catchment areas are available both to the east coast cities, which are in the zone with less than 30 in. in at least 30% of the years, and to Glasgow and the industrial west, which are in an intermediate rainfall zone. Even in accessible areas considerable potential supplies remain untapped. (A. T. A. L.)

4. Vegetation.—The flora of Scotland is much affected by the varied climate to be found in so small a country, by the varied geology and physiography, and by the activities of man. The Atlantic climate of the west coast and islands is warm and wet, and the rocks are mainly poor and acidic. On the general covering of peat with comparatively little glacial drift beneath it grows a sour herbage of sedges with some heather and such northern shrubs as bearberry, crowberry, and blueberry. An exception is a narrow strip along the west coast of the Hebrides and some of the mainland, where shell sand of high basic content has been washed up by the ocean and blown inland; behind the marram-covered dunes is a flatter expanse of sandy soil with stable grassland and many lime-loving flowers. Tree growth is sparse on the western coasts where winds are excessive in frequency and strength, but where there is shelter birch woods grow readily, with mountain ash and willow interspersed. Vestigial oak and pine may also be found along the fjordlike sea lochs of the mainland. The tree line is low in Scotland, rising from 500 ft. (150 m.) near the west coast to around 2,000 ft. (600 m.) in central Scotland. The west Highlands and islands show vestiges of a Lusitanian flora, for example, pale butterwort, dwarf cicendia, and the moss *Myurium hebridorum*.

Glacial drift is commoner across the Grampian Hills, toward the east, and in the Southern Uplands, so heather is much commoner on the still acidic moors and may attain to an almost unbroken stand. These heather moors are an example of arrested succession, for if left to themselves they would gradually revert to woodland of birch and Scots pine, with oak in the better situations. Mankind has left very little pristine oak and pine forest in Scotland, and such stretches as remain are subject to earnest efforts toward conservation. The moors are grazed by sheep and are burnt periodically. This form of husbandry keeps the heather young and

TOM HOLLYMAN FROM PHOTO RESEARCHERS

(Left) Out shooting in the Highlands. (Above) A salmon landed from a Scottish stream

prevents regeneration of forest, but a consequence in the west is the serious spread of the bracken fern. Sheep and controlled burning on heather moors favour the density of red grouse, a valued object of sport. The upper 1,000 ft. of the hills of the Highlands, rising to over 4,000 ft., may be said to carry a more or less pristine flora of boreal mountain grassland with many saxifrages and such miniature shrubs as *Loiseleuria* and dwarf willow. Areas of serpulite grit, including Ben Lawers (3,984 ft.), have a rich Alpine flora. Some of the eastern hills of the Southern Uplands carry a grassy flora which under sheep and burning is moving toward a predominance of matgrass.

In both the Highlands and the Southern Uplands a good deal of land is being afforested, mostly with exotic conifers. Scotland, early isolated from Europe, has but three species, Scots pine, juniper, and, uncommonly, the yew. Larch was introduced about 1725, followed by Norway spruce and many west coast species from North America.

The eastern side of Scotland is highly farmed, much land being on the Old Red Sandstone; natural grassland and untouched places are few, the sea cliffs and some estuarine situations being the only sites which may be said to carry a natural flora. The central plain is in the same case, but there are a few bogs here which hold distinctive plants such as the low evergreen shrubs, marsh andromeda, and Labrador tea. It is still not unusual to find plants new to Scotland which are common in the subarctic.

5. Animal Life.—The fauna of Scotland is an enviable one for so small a country. The largest wild mammal is the Atlantic gray seal, which is more numerous off Scottish coasts than anywhere else. The Island of North Rona, less than half a square mile in extent, lying nearly 50 mi. (80 km.) NW of Cape Wrath, has a stock of thousands at the autumn breeding season. The common seal is fairly generally distributed and locally numerous. The red deer is truly wild in Scotland, one-eighth of the whole country being scheduled as deer forest, and the species ranges over another 1,000,000 ac. (404,700 ha.) of sheep ground. The total number may be almost 150,000. Roe deer are found wherever there are woods or scrub. Feral goats (goats that have gone wild) occur in many deer forests and on a few small islands. Foxes and badgers are common in Scotland. Both species prey extensively on the rabbit, an introduced animal, which, as far as the northern Highlands are concerned, was introduced as late as 1845. The wildcat has increased and widened its range in the first half of the 20th century.

Otters are common on the river systems, and on small islands they may live wholly on sea fish. The polecat is extremely rare and for some time was considered extinct. Pine martens are probably more numerous than at the turn of the century and may be expected to increase with reafforestation. Nevertheless, there are more pine martens in treeless northwest Sutherland than elsewhere in Scotland. The mountain hare is distinctly cyclic in population and is a pest on hill-sheep ground in peak years. The brown hare occurs where there is true soil and agricultural husbandry, not on the hills and peat moors.

The early isolation of various island groups has led to the evolution of distinct types of some animals, notably the voles. Differentiation has gone far enough for subspecific rank to be accorded. Thus, there are the Orkney, Raasay, and Mull subspecies of field or bank voles. The same phenomenon is evident in some birds. There are St. Kilda, Hebridean, and Shetland wrens and Hebridean starlings and thrushes. The Island of Soay in the St. Kilda group holds a pure stock of a primitive, brown, short-tailed sheep of mouflon type. The original animals are thought to have been of Neolithic origin.

Scotland lost the brown bear in the 9th century, the elk and the reindeer in the 12th, and the beaver in the 16th. These animals could not subsist adequately in Scotland now for the vegetation has so greatly changed. The last wolf was killed in Inverness County in 1743.

The bird life of Scotland is rich, though many species found farther south do not occur. Its outstanding features are the numerous seabird cliffs thickly populated by auks, fulmars, and gannets; the existence of more than 100 pairs of golden eagles; the breeding colonies of the night-flying Leach's petrel on four small, remote islets; and the sight and sounds of greenshanks and black-throated divers in the deer-forest country. Graylag geese still breed in the Hebrides, and certain places such as Loch Leven are focal points in the wintering of other northern geese.

Most Scottish rivers are run by salmon and sea trout, and many lochs hold distinct races of char. Pike are in many river systems by accident or design, but the muddy-water fish common to English rivers are for the most part absent from Scotland.

Biological exploration of the invertebrate life of Scotland is far from complete, and the life histories of many insects already known have not been determined. Summer visitors to the west Highlands appear intensely aware of the tiny biting midges.

(F. F. DG.)

II. GEOGRAPHICAL REGIONS

1. The Highlands and Islands are areas concerned predominantly with extensive pastoral farming on hilly rough grazings, with relatively small proportions of improved land, partly arable, on lower ground. Within this regional unity, however, the occurrence of subregions reflects the diversity in climate, scenery, and economy. Factors contributing to the variety are, for example, the incidence of Gaelic speech, crofting, fishing, and weaving. There are intimate relations with the richer country of the eastern Lowlands, particularly north of Glen More.

The windswept archipelagoes of Orkney and then Shetland (*q.v.*) lie northeast of Duncansby Head in Caithness. The Shetlands possess an astringent charm, with their low schistose hills amid fjords only three hours by air from Renfrew, their many crofter-fishermen with lingering cultural affinities with Scandinavia rather than Gaeldom, their slender resources of declining fishing, of tourism, and knitwear using fine local wool. The Orkney Islands (*q.v.*) have warmer soils formed from the Old Red Sandstone; the people are quick to adapt their small farms to modern techniques with their reseeded clover pastures, large beef-cattle and egg exports, and holiday catering.

The Outer Hebrides extend from Lewis-and-Harris to Barra. Gaelic is still spoken by many of the crofters. The islands are low and windswept with ice-scoured, hummocky, gneissic hills and peat-capped boulder-clay hollows partly stripped for cultivation. The good pastures on the machairs of windblown shell sand on the western shores are still in places periodically plowed in strips, allocated to crofting families by lot, and herds are pastured in summer on the high shielings. Vital subsidiary occupations are herring fishing, which is on the decline; tweed making, increasing in Harris and elsewhere; lobster catching for export by air; seaweed harvesting around Lochmaddy for processing into cattle food; and production of fertilizers.

The Inner Hebrides from Islay to Skye are somewhat similar but with distinctive mountains: the Cuillin Hills of Skye, dissected glaciated bosses of gabbro, and Ben More in Mull, a much-eroded volcanic crater complex. There are relatively good pastures on the basalt lavas of Skye, Mull, and western Morven. Mean annual rainfall rises from 40 in. (1,000 mm.) to over 80 in. near the hills, and the limit of cultivation is about 400 ft. (122 m.). North of Jura the islands and adjacent mainland areas have sporting estates and large sheep farms, and again many crofting townships, focused on well-drained, easily tilled raised beaches, but largely inhabited by older people and epitomizing the many problems of crofting. The main problems are overcrowding on small coastal holdings following the clearance of the inland glens for sheep, too few truly economic family holdings even on government estates bought for resettlement, and paucity or failure of subsidiary occupations like fishing, whisky distilling, tweed making, aluminum refining, and light engineering. Forestry Commission plantations, sporting estates, tourism, and air services have helped little, and as yet roads and public services are difficult to finance for an aging population in an area of low ratable values; but it has been possible to provide several small hydroelectric plants to serve local populations. The southern islands, with most of Argyll, have enclosed stock farms rather than small crofts, with good arable stock farming and dairying on the lower ground, yet emigration remains high; Islay lost half its population between 1880 and 1950. Air routes serve Campbeltown and Tobermory.

NOEL HABGOOD FROM PHOTO RESEARCHERS

THE HILLS OF TROTTERNISH, ON THE ISLE OF SKYE, SEEN FROM STAFFIN

Roughly bisecting the Highlands and controlled by a lateral fault line, Glen More runs northeast from Fort William to Inverness, strung with glacially gouged lochs, including Loch Ness. North of Glen More stretch the Northwest Highlands, with roughly longitudinal belts of distinctive scenery. A western coastal fringe consists of low hummocky Archean gneiss backed by stepped precipices of brown Torridonian sandstone, dissected into mountains sometimes capped by white Cambrian quartzite. Farther eastward an intermittent belt of white Cambrian limestone stretches from Durness near Cape Wrath to Strath Oykell, topped by green turf, followed by the complex belt near the Moine Thrust plane of the Caledonian orogenesis, including some notable peaks like Ben More Assynt (3,273 ft. [998 m.]), and a centre of ice dispersion in Quaternary times, as witness many ice-gouged ribbon lakes (Lochs Shiel, Fannich, etc.) and fjords (Lochs Duich, Hourn, etc.). The great central Moine schist belt stretches from Strath Halladale to Glen Urquhart and in the west from Whiten Head to Morven, with its sombre level moorlands, occasional monadnock hills, and softer glens often trending east, northeast, or southeast, with a little residual oak wood, cultivation ridges antedating the clearances, a little arable for large sheep farms of up to 30,000 ac. (12,100 ha.), and in places Forestry Commission plantations. Finally, the conical, heathery Old Red Sandstone conglomerate hills of the east merge into the Lowlands covered in warm red boulder clay and the coastal raised beaches with lighter soils. There the mean annual rainfall of as little as 25 in. (635 mm.), high sunshine especially from March to June, and long summer daylight all favour arable stock farming, with a little barley for sale, mainly on small family farms. These Lowlands are an area of greater development generally, with much of the road and rail network, the ratable value, and the population, and include the towns of the northern mainland, from Wick and Thurso through Helmsdale and Dornoch, Dingwall, and Fortrose to Inverness, the regional capital.

South of Glen More lie the Grampian Highlands, with many individual massifs such as the Monadhliath Mountains and the Cairngorms. The highest peaks overlook dissected plateaus of about 3,000 ft. which cut across the northeast to southwest trending schists of the Moine series in the north and the Dalradian series in the south, both of which were tightly folded in the Caledonian orogenesis. Again glens trending east, northeast, or southeast divide the country into blocks, sometimes of distinctive rock type, and generally more dissected into conical hills in the wetter west. The conical peaks and dark andesite lava crags of Glencoe contrast with the granite massifs, generally rounded but sometimes deeply corried as on Ben Nevis (4,406 ft.; 1,343 m.) with its crown of andesite and deep northern corries; shapely Ben Cruachan, whose granite extends under the peat and boulder clay; the wilderness of bogs and lochans of the Moor of Rannoch; the Cairngorms, Lochnagar, and the Deeside Hills with wide stretches over 4,000 ft., dropping in precipices to the northern corries; the smaller Ben Rinnes, standing between the moors and the Moray Lowlands. Again two lines of quartzose grit hills, often conical, stretch from Beinn a Ghlo and Schiehallion to the rounded Paps of Jura, and near the Highland edge from Ben Venue to Ben Chonzie and beyond. From the high precipitation area in the west, Quaternary glaciers gouged outward, forming sea-lochs, *e.g.*, Fyne, Leven, and freshwater lochs, *e.g.*, Awe, Lomond, Rannoch, before sweeping, still maintaining their powers of erosion and deposition, into the mid-Lowlands; farther east glens were broadened but high plateaus

protected by névé were less affected by ice erosion, and lochs are fewer and smaller. Large sheep farms using Border breeds, Blackface and Cheviot, have dominated farming there since the change from black cattle export in the 18th and early 19th centuries. Pastures have largely deteriorated, because of the invasion of bracken in the low winter pastures and the scarcity of shepherds for isolated hirsels (one man's charge of sheep and hill). The Forestry Commission owns much land, especially in the west, while the east, less dissected, drier, more heathery, has deer forests and grouse moors also deteriorating somewhat owing to overburning. Few medieval castles survive, but there are many 18th- and mock baronial 19th-century mansions, and estate villages like Blair Atholl, Pitlochry, or Tomintoul (at 1,160 ft.); some have grown into small towns. Tourist trade came early to towns accessible to Glasgow like Rothesay and Dunoon, but in the mid-20th century it was growing in centres like Newtonmore and Kingussie, Oban and Fort William. Main regional centres like Inverness, Perth, and Aberdeen lie rather outside the Highlands near the mouths of major straths; but Inverness is so much the capital of the north that it is included in this Highland region. It lies at the mouth of the deep, clear, swift River Ness, its late-18th-century castle and barracks overlooking wide clean streets, many churches, and peripheral factories.

2. The Northeast Region comprises the eastern Lowlands from Stonehaven to Inverness, largely influenced by Aberdeen. This region mainly forms a tract of arable stock farming, often on small family farms, with intimate relations with Highland country farther west, via small to medium-sized market towns; fishing and boatbuilding, distilling, and the holiday trade are of varying importance.

East of Inverness stretch the dry, sunny Moray Firth Lowlands with family farms practising variations on a six-course rotation, including short grass leys, but mainly concerned with arable stock farming for beef production. In the west, warm, fertile Old Red Sandstone boulder clays yield some barley often sold to whisky distilleries; the 9,500 ac. (3,845 ha.) of the Culbin sands, where about 1670–95 an estate was overwhelmed by blown sand, are now reclaimed by the Forestry Commission. East of Buckie on colder boulder clay over Highland rocks there is increased emphasis on fodder and Aberdeen Angus cattle, continued on the bleak, windswept Buchan Plateau, the northeast shoulder of Scotland, where the rotation is maintained in somewhat harsh conditions. Some coastal settlements are still active in fishing (Lossiemouth, Buckie, Macduff, Fraserburgh), a few in boatbuilding; Peterhead also processes Norwegian granite, while local quarrying is declining, and others depend more on holiday trade (Nairn, Findhorn, Burghead, Portsoy). On the coast or a little inland is a line of county and market towns with solid stone buildings lining wide streets (Nairn, Forres, Elgin, Fochabers, Banff, Turriff) and inland again a further line (Aberlour, Dufftown, Keith, Huntly) on a harsher but green plateau at 1,000–1,200 ft. with many individually held crofts, rearing beef calves sold young for fattening to Lowland farms. The hinterland of Aberdeen, the regional capital, includes the lower Don and Deeside high-grade arable and stock-farming region and markets like Banchory and Inverurie; but it embraces the whole north of Scotland for university education. South of Aberdeen the Kincardine Plateau resembles Buchan; while on the coast declining fishing villages are turning to the tourist trade. Stonehaven, the county town, lies almost on the Highland boundary fault, a reminder in turning to the mid-Lowlands region that Kincardine, like several other counties and other man-made regions, straddles the geological and landscape boundary and does not coincide with the natural region.

3. The Mid-Lowlands, containing three-quarters of Scotland's population and much of the urban and industrial scene, nevertheless include quiet arable-farming landscapes. In the east farms are oriented predominantly to cash cropping with stock fattening, in the west more to dairying. The many uplands included in the mid-Lowlands are used for hill-sheep farming, reservoir catchments, and sporting and recreational space. The urban scene in the west is dominated by the heavy industrial complex, built up around shipping and shipbuilding. The townscapes of Glasgow and the surrounding towns contain almost half the country's population. In the east is the capital Edinburgh, and considerable though lighter industry, the growing coalfields of Fife and Midlothian, and several sizable seaports. The mid-Lowlands is a core region, extending its sphere of influence in many ways over the whole country, and within which lies much diversity and contrast.

Southwest of Stonehaven lies a fertile vale, Howe of the Mearns and Strathmore, with arable stock farms producing some cereals on warm mixed Old Red Sandstone boulder-clay soils, with soft fruit on fluvioglacial sands around Blairgowrie, and a line of market towns, Brechin, Forfar, and Coupar-Angus, with textiles or other small industry. Eastward rise the andesite lava hills of the Sidlaws, falling to a dry, fertile coastal shelf of Old Red Sandstone boulder clay, with raised beaches and the cuspate headland of Buddon Ness, the shore fringed by fishing and holiday towns (Inverbervie, Carnoustie, Arbroath, and Montrose) with small industries including jute. The Sidlaws' southern slope to the Tay gives views over the firth to the compact centre and sprawling suburbs of Dundee, a city of jam and jute, once an important centre for whaling and now for government-encouraged light industries which are supplanting the formerly dominant jute industry.

From Strathmore similar vales run southwest to the Firth of Clyde, between the conical, heathery, Old Red Sandstone conglomerate hills along the Highland edge, and the line of moorland hills (1,400–1,700 ft.) of lava, continuing the line of the Sidlaw, Ochil, and Kilsyth hills, Campsie Fells, and Dumbarton Hills. Arable stock farming with cereals gives way to increased fodder production and dairying as mean annual rainfall increases westward from 30–35 in. to 45–50 in. Flanders Moss, however, remains partly unreclaimed from deep peat. Towns are often at the mouth of a Highland glen or strath tributary to them. They can be grouped as market towns and resorts (Callender, Crieff); former royal cities, remaining regional capitals (Perth, Stirling); residential towns for schools and retirement (Dunblane, Bridge of Allan); dormitories for Glasgow (Strathblane, Milngavie, Lennoxtown). On the Clyde are Helensburgh, a resort and dormitory town, the outport of Port Glasgow, and Dumbarton with shipyards and engineering beneath its ancient castle crowning volcanic crags. By the Leven flowing from Loch Lomond are textile-finishing centres and an industrial estate. Both banks of the dredged upper Clyde estuary are lined with famous shipbuilding and engineering towns; Clydebank builds ships and manufactures sewing machines. The rolling drumlins on which Glasgow is built overlie the fringe of the major syncline of Carboniferous rocks. In these rocks are the coal and blackband ironstone deposits which were the foundation of the heavy industry of the whole region. Coal production is still considerable though declining and the ironstone is no longer important; exhaustion of these resources raises many problems of transfer of redundant mining population following the reorientation of industry (see *Economy*, below).

Glasgow, with one-fifth of Scotland's population, is the commercial and industrial, though not the political, capital; its many industries include engineering of almost every kind. It is equally significant as the focus of the congeries of industrial towns comprising an eastern group (Kirkintilloch, Airdrie, Coatbridge, Motherwell, Wishaw, Hamilton) and a western group (Barrhead, Paisley, Johnstone). The eastern group is engaged in coal, iron, and steel production and heavy engineering; the western group in the manufacture of cotton thread, preserves, and sanitary ware, general engineering, and the left-bank shipyards. More than a dozen industrial estates now complement the heavy industry with varied manufactures ranging from lingerie to aero engines. The conurbation strongly influences coastal resorts in Argyll, Bute, Arran, and Ayr; while Prestwick has an international airport, seldom fog-bound. Ayr, Troon, Ardrossan, and Girvan, however, depend on the Ayr coalfield as the basis of their coal exports and industries. Production from this coalfield is still expanding, and it has its own large and small industrial towns (Kilmarnock, engineering and whisky; Darvel, lace and carpets). Links with Glasgow are strong even in farming. This is reflected in the growth of the dairy industry, including Dunlop cheese originally from remote farms, and the related development of Ayrshire cattle. These

cattle yield well from only moderate-quality improved upland pastures. Trade has developed in pedigree and attested tubercle-free stock, in bacon production, early potato crops, and strawberry growing on the light soils and in the mild climate of the west coast raised beaches. Similarly, across the volcanic heights, the central Clyde Valley produces soft and tree fruit, tomatoes, and greenhouse products from Strathaven to Carluke; upstream is the Abington-Lanark-Lesmahagow dairy belt, where cheese making has moved from remote farm to factory during the 20th century.

North of the coal towns of Coatbridge, Airdrie, and Armadale lies the peat-covered Slamannan Plateau, with abandoned coal workings and declining small towns which the introduction of light industry is reviving. North again the foundries of Falkirk, Carron, Larbert, and Bonnybridge produce domestic stoves, grates, etc. Grangemouth, a rising Firth of Forth seaport, has well-developed oil-refining and chemical industries originally based on the almost extinct oil-shale mining of the Bathgate area on the east of the Carboniferous syncline; petroleum is now imported by tanker via pipeline from Finnart on Loch Long. Eastward, Bo'ness is a small timber port once serving Linlithgow, an ancient royal town. Across the Forth, on the north of the coal basin lies Alloa, a small port with brewing, glassmaking, and engineering, and at the foot of the Ochils lie the small paper towns of Alva and Tillicoultry. Farming persists between industrial centres, dairying on the low ground, and sheep on the uplands.

South of the Firth of Tay, Fife has a series of contrasting east-west belts; a coastal fringe of good arable land, with dormitory and resort towns for Dundee; the lava hills of the eastern Ochils; the dry and sunny Howe of Fife, its boulder-clay loams and fluvioglacial sands under neat arable farms yielding wheat, barley for Markinch distillery, sugar beet for the factory at Cupar, and soft fruit and peas for quick freezing. This pattern extends to the East Neuk where ancient St. Andrews has Scotland's oldest university and the famous coastal golf links, while fishing villages cater for holiday traffic and have some boatbuilding. Farther south are lava hills in the Lomonds and the ridge east toward Fife Ness, and a third line of lavas, the Cleish Hills, and the ridge toward Kirkcaldy. The western hills and the Ochils hem in the Kinross Basin, with the famous angling of Loch Leven amid quiet farming country akin to that of the Howe of Fife. Under the coastal Lowlands fronting the Forth is the East Fife coalfield, with early exploitation around Cowdenbeath and Lochgelly behind the coal ports of Buckhaven, Methil, and Leven, but with large reserves in the east where a sharp syncline continues the Midlothian field. Important expansion in the 1950s was marked by the new town of Glenrothes, but later severe mining difficulties were encountered. Heavier boulder-clay soils are in short grass leys, with increased dairying stimulated by nearby industrial and mining towns. Dunfermline, with a former royal palace and ruined abbey, is a linen centre now turning to man-made fibres, while Kirkcaldy's coarse linen trade is dwarfed by the modern linoleum manufacture comprising most of Britain's output. Burntisland has a small shipyard and produces alumina from imported bauxite for refining at Kinlochleven. South of the Forth, Edinburgh Castle on its volcanic plug controlled a gap of only a few miles between the Pentland Hills and the port of Leith; the city retains residual functions as capital, along with varied services and industries. It spread rapidly in 1920–60 from a compact nucleus of distinctive character, now filling the Lowland gap. On nearby raised beaches and Lowland plateaus are market gardening and intensive farming for cereals, potatoes, and fodder largely for dairy herds. The breezy Pentlands give recreation space and water reservoirs; east lies a coalfield amid farming country, still expanding around Dalkeith and Gorebridge; deep seams in a sharp syncline extend to Tranent in East Lothian. Penicuik, Bonnyrigg, and Musselburgh on the Esk manufacture paper, carpets, and wire. East of the coalfield the dry, fertile East Lothian Lowland is intensively farmed for cereals, potatoes, and fodder for dairy and fattening cattle. Haddington, its small county and market town on the Tyne, with some woolen manufacturing, is expanding to take some of Glasgow's overspill population. Dormitory and resort towns fringe the coast; fishing is declining.

4. The Southern Uplands are dominated by hill-sheep farming on smooth rounded green hills; the terrain is wilder in the west. There are close relations with the dairying country of the dales and coastal Lowlands of the west, and the arable cash-cropping farms with stock fattening in the lower Tweed Basin. The many small market towns are important local centres of services and amenities, many having tweed mills or other small industries. The following paragraphs give broad indications of diversity within unity in this region.

Over the whole width of the country erosion surfaces cut across slaty rocks. These surfaces are more dissected in the wetter west where the moorland vegetation is greener and less heathery, though grassy hills occur throughout. Flocks are mainly Cheviot sheep, with Blackface on heather moors, also used as grouse moors. Most streams are valued for salmon and trout. Higher mean annual rainfall in the west (50–90 in.) and the more rugged glaciated topography, especially in Galloway's granite massifs, led to locally important hydroelectric development between the two world wars. The head of Annandale echoes this wilder scenery, with several small glacially gouged lochs and the Grey Mare's Tail Waterfall. Eastward the scenery softens to rounded hills, névé-protected in glacial times, and wide expanses of level moorland. The Lowlands around the western hills and the broad dales of Nith and Annan which penetrate them are largely under arable grass farming for dairying, now extending on to breezy plateaus up to 800 ft. None of the many former ports on Solway remain really active, but Stranraer on Loch Ryan is a packet station for Larne, Ire. Glenluce, Wigtown, and Castle Douglas are small market, service, and holiday centres. Dumfries, with growing industry (textiles, chemicals, milk canning), is spreading rapidly along the Nith. Annandale has several market towns and is an important routeway, linked south to the Carlisle Lowland and north over Beattock Summit (1,028 ft.) to Glasgow and Edinburgh.

On the rolling drumlins and fluvioglacial sands of the Tweeddale Lowlands, between the Southern Uplands and the Cheviot and the Border hills, are arable farms producing some barley and wheat as well as feeding beef cattle and heavy sheep like Border Leicesters. Intermediate plateaus at 500–600 ft., with widely improved grassland, retain peat mosses in places. Purely market towns exist (Newtown St. Boswells), but most also have textile industries with Galashiels as the centre. The tourist industry is important, especially at Peebles for the Sir Walter Scott country, Melrose and Jedburgh with ruined medieval abbeys, and at Kelso which is a renowned sheep market. Most towns and valleys retain intense local patriotism, a legacy of Border wars and raids. On higher ground in central Berwick lies the small quiet county town of Duns. (A. T. A. L.)

III. THE PEOPLE

In this age of quickened mobility of population and innovation in both material and nonmaterial culture, Scotland, like other countries, is tending to lose regional and local distinctiveness in its people. It would be futile to seek any close correlation of race, language, and religion over the country as a whole, but something can be learned of the stages leading toward the amalgam of today by the study of communities long resident in isolated localities. In such communities language is often distinctive, and on larger islands the community of each glen or sweeping bay line may have an accent and physiognomy slightly different from those of the next. Some Gaelic (*see* CELTIC LANGUAGES) is still spoken, mainly in the Hebrides and by older people on the northwest coast; in a Roman Catholic crofting islet in the Outer Hebrides one woman recently recorded some 900 proverbs and 450 unpublished songs and variants. In that area the people are mostly small, dark, and gray-eyed (though a few are tall, fair-skinned, and red-haired) and there are residuals of communal labour.

A journey in Scottish backwaters is in fact an experience of living history. This may be sensed even in the busy Scottish city. Within the modern suburban sprawl there is a preponderance of single-storied dwellings, unusual in neighbouring England, and local authority housing more often consists of flats. Both tendencies derive from a long tradition of living on one floor, in the inner

rings of tall stone tenement blocks, many of which remain today as middle-class flats, while others are occupied by manual workers living in more cramped conditions, and the oldest are condemned slums. Tenements are in turn descended from tall "lands or tenements" which filled up the former garden strips of a few central streets, sometimes, as in Edinburgh, within a wall. The high death rates associated with such overcrowding have fallen steeply but housing and health still lag behind southeast Britain. Tenement dwelling inculcated virtues and failings: the virtue of minding one's own business, sometimes perhaps carried to excess in the suspicion of new, even if friendly, contact—in the east at any rate; or the bitter feuds resulting from the need to share facilities and stairs. There remain well-marked, though fluid, social stratifications and a multiplicity of urban accents. In the countryside, Lowland Scots accents are again diversified, but with less marked social stratification, and there is particular separatism in mining and fishing communities.

TOM HOLLYMAN FROM PHOTO RESEARCHERS

SCOTTISH DANCER

Woven into the complex, flowing tapestry of the present are some of the following strands: the spread of the Neolithic farmers—mainly short, dark brunets with gray eyes, who by Roman times were speaking Brythonic Celtic and are commonly if controversially referred to as Picts; from the inflow of Beaker folk in the early Bronze Age there came an element of taller, roundheaded people; there may even be some genetic heritage from the Mesolithic hunters and fishers; around A.D. 500 came a movement of Goidelic Celtic-speaking Scots from Ireland, ultimately giving Scotland its name and apparently leading to the displacement of the Brythonic tongue, and bringing important elements of culture and communal practices discernible today; at the same time, Anglo-Saxon invasions brought less brunet, possibly taller people with techniques for clearing the damp, dense forest for open fields and long-furrow agriculture as in England; they probably intermingled with the Celts (there seems to be a remarkable parallelism between the farm-touns [towns] and the Kirk-toun of a Lowland parish, and the ordinary bal' [town] and the clachan [church hamlet] of a Highland parish); later the Norse invasions affected particularly the Orkneys, Shetlands, and Hebrides and the coastal belt of the west, northwest, and northeast mainland, and brought a fresh element of tall blonds or redheads and Norse as the dominant tongue—"Norn" survived in Shetland until the 19th century—as well as legacies of technology and farming practice such as the saeter or summer pasture (rendered in Gaelic as *seadir* and in Anglo-Gaelic as *shader*).

Norman feudalism, where it had operated, and, much later, the commercial, agricultural, and industrial revolutions resulted in rigid social stratification—tempered, however, by some sense of community in a harsh land where natural calamity could strike rulers and ruled alike. On the other hand the Reformation and the ascendancy of the initially rigid Calvinistic Presbyterianism brought also a tradition of independent thought and argument, with the acceptance of a man for his own worth as an elder of the kirk. It was perhaps no accident that at a time of technical change and increasing social tensions Robert Burns (*q.v.*) rose from a poor, small farming family of the west.

The growth of capitalism brought the Lowland sheep farmer into the Highlands as agent of the cash nexus following the military pacification in the 18th century. The clan was destroyed. Revolutionary socioeconomic changes brought a population increase at first, but later sharp depopulation was given speed and poignancy by the Highland clearances and the 1845–47 famine. In parts the Highlands have a top-heavy age structure, and in some sense a wounded and dependent apathy, which shows only local signs of being overcome from within the communities themselves. Tartans, a clan badge, bagpipe music, and some remaining chiefs are the last rallying points for residual clan loyalty, sentiment, and much sentimentality; overseas they are uneasy bedfellows with an imperfect knowledge of Burns as the focus for Caledonian societies. However, nowhere in Britain does the economic cooperative movement surpass that of the Shetlands, Orkneys, and Hebrides.

The labour-hungry 19th century saw wave after wave of initially poor and ignorant Roman Catholic Irish immigrants, who had vigour and charm and an ability to make good. On Clydeside their group cohesion is one origin of the passionate Celtic (Catholic) and Rangers (Protestant) football rivalries of today. Irish labour is attracted by hydroelectric plans and is acquiring skill; more recently West Indians have been taking the place of Irish on Clydeside, while Indian and Pakistani itinerant merchants are found, even in the Highlands and islands. (AR. G.; A. T. A. L.)

IV. ARCHAEOLOGY

1. Stone and Bronze Ages.—The oldest satisfactory evidence of men in Scotland is provided by Mesolithic flints. Some found along the southwest coast may go back to the 5th millennium B.C., but probably most belong to near the end (*c.* 2700 B.C.) of the period. Makers of microliths may be presumed in most coastal and lower river valleys. More is known about the Obanians whose cave shelters and large shell middens are found on the west coast and on Oronsay Island. They evidently used seagoing boats. Their antler and bone barbed points for harpoons suggest derivation from those of the Azilians (descendants of the Magdalenians) in France, though the relation of the sites to the raised beaches (see *Physical Geography*, above) suggests that they should be dated to the end of the Atlantic climatic phase, scarcely before 3000 B.C. Antler mattocks from the western middens and from whale carcasses near Stirling mark contact with the Baltic Ertebolle culture.

The incoming Neolithic stock raisers and agriculturists cleared the woodlands with their still ubiquitous stone axes. Their pottery and earthen burial mounds show penetration from Yorkshire to the Moray Firth. It is not yet known whether it was the first Neolithic colonists in the west who introduced megalithic chambered tombs of the gallery grave type, nor how long these tombs preceded the type with passage and chamber distinct, from Iberia and Eire, found in the Hebrides but most fully developed in Caithness and in Orkney, which in Maeshowe has the finest chambered tomb in Britain.

Late in the Neolithic Period, about 2000 B.C., communities of quite uncertain origin developed in England and also went north. The stone ax trade may have been in their hands. In Orkney they left the most complete 2nd millennium settlement known in northern Europe, at Skara Brae (*q.v.*). Quite different equipment and stone houses, scattered among fields, with poor chambered tombs and a large public building, survive from a later but still stone-using population in Shetland. In some close, probably dominant, relationship to these communities were the Beaker immigrants, whose characteristic pots and short-skulled skeletons occur in single stone-lined graves throughout eastern Scotland. Some of their pottery indicates an immediate origin on the lower Rhine. They reached the west before the chambered tombs were given up. If not themselves copper prospectors and traders in bronze implements, they must have promoted these activities. Some of the circles of standing stones are their sacred monuments.

From about 1500 B.C. there was a pause in immigration and a long period apparently of pastoral stagnation during which trade increased, especially with Ireland. The various peoples coalesced. Shorter pots, usually called "food vessels," replaced beakers in the short cist graves, often with elaborate jet necklaces. Then cremation became dominant, with various types of large urn found singly and in cemeteries; occasional beads of blue faïence seem to mark a burst of trade with the Mediterranean. Unfortunately

identifiable burials cease before 1200 B.C. and are almost entirely absent for the next 1,700 years or more. No dwellings of the makers of food vessels or of cinerary urns are yet known.

The swords and larger spearheads that, with socketed bronze axes, mark the beginning of the Scottish Late Bronze Age about 900 B.C. indicate warfare if not renewed invasions. While metal objects traded within the British Isles were increasing in number, variety, and size, a few ornaments in cached hoards suggest direct contacts between northeastern Scotland and the north European mainland both in the 7th and the 6th centuries B.C. A domestic bucket urn pottery, though associated with these ornaments, may have had a long earlier history in Ireland. The only Scottish Late Bronze Age settlement, with new pottery denoting immigrants, is at Jarlshof in Shetland, which has the longest sequence of houses and pottery in Britain.

2. Iron Age (After 500 B.C.).—Stockades and clusters of round timber houses underlie many of the Iron Age earthwork or stone forts in southern Scotland. They mark the beginning of the pattern of Celtic tribalism found in Roman times. Later there were numerous timber-laced stone forts, which often left vitrified remains when burned down. Multiple-rampart fortifications came later; some were just homesteads, as were artificial "crannogs" (defensive islands) in lochs. The Belgic and Roman invasions of England intensified northward population pressure, vividly illustrated by the hundreds of "brochs" (stone towers) peculiar to the extreme north and west, such as that at Mousa in Shetland. The few fortified settlements that can be called towns lie south of the Forth, notably that on Traprain Law near Haddington, which flourished mainly while the Romans held Britain.

The strategy of the Roman army which campaigned under Agricola from A.D. 80 remains unclear despite recent discoveries. Forts along the Highland line and in southern Scotland were held till A.D. 100, more than 12 years after the garrison of Britain was decreased and the consequent removal of the great timber buildings of the unfinished legionary fortress at Inchtuthil near Dunkeld in Perth. The Antonine frontier reorganization after 139 has left an elaborate system of forts, fortlets, and roads south of its Forth-Clyde Wall, built of turf behind a great ditch, and some forts north into the county of Perth. This was finally overthrown about 196 by the Caledonii and their allies. The few brochs south of the Forth, and subterranean chambers there, "earth-houses" or "weems" (most common in Angus, north of the Tay), may represent this alliance. But the frontier was stabilized, probably by buffer states, after Severus' punitive expeditions. To these are now ascribed a legionary headquarters at Carpow on the Tay, and a chain of great temporary camps reaching as far as the Moray Firth. Traprain Law provides evidence for Roman trade north of Hadrian's Wall in the 3rd and 4th centuries; but also, in the treasure of pagan and Christian silverware found there in 1919, for the raiding which accompanied the collapse of the empire.

Romanization continued after the legions left Britain; the first native inscriptions in Latin are on 5th- and 6th-century Christian tombstones. Recent excavations claim to have unearthed what may be actual buildings of the historic missionaries; of St. Ninian and St. Columba (*qq.v.*) at Whithorn and at Iona respectively. Finds from fortifications and from crannogs bear out close relations with Ireland and include 8th-century pottery from the Continent. Metalworking reached a very high standard, notably in the gold filigree animals on the silver brooch found at Hunterston on the Clyde estuary. The kingdoms of Scots and Picts (united about 843–844), Britons and Anglo-Saxons, are as yet distinguished archaeologically only by their sculptured monuments. Pictish sculpture, at first unexplained incised linear symbols and animals, and later cross slabs with scenes and ornament in relief, is a very remarkable artistic achievement, even if inspired by Anglo-Saxon and Roman art. One of the earliest and finest of the Anglo-Saxon free-standing crosses is at Ruthwell in Dumfries (8th century). The Viking incursions and colonization, marked by burials, some excavated settlements, and (in the 10th century) hoards of silver ornaments and Anglo-Saxon coins in the western and northern isles, led to a general impoverishment. The latest pre-Norman sculpture in southern Scotland is barbarous. (R. B. K. S.)

V. HISTORY

A. Early History

1. The Settlement of Scotland.—The earliest writings on the history of Scotland are the accounts of the several Roman expeditions; but archaeological evidence shows that many invasions and settlements took place in prehistoric times (see *Archaeology*, above). When the Romans first entered what is now Scotland, they found a tribal society dominated as far north as Aberdeenshire by an iron-using aristocracy, which had probably come fairly recently from the Continent. Farther to the north and west, the inhabitants retained a more primitive culture. The geographer Ptolemy gives the names of some of the tribes in his map; of which the most important were the Novantae in Galloway, the Selgovae in the Tweed Valley, the Votadini in Lothian and the Merse, the Damnonii around the estuary of the Clyde, and the Caledonii apparently along the Great Glen.

The Romans themselves left little mark in Scotland. Agricola, the governor of Roman Britain from A.D. 77 or 78 to 83 or 84, invaded the country, built numerous forts, and marched probably at least as far north as Strathmore before winning in 83 or 84 his great battle of Mons Graupius, the site of which remains uncertain. Although many of his forts were still occupied after his recall, they were abandoned before long, perhaps around A.D. 100. The defense of the northern frontier of Roman Britain was difficult, however, and the Romans returned in 142 to build the Antonine Wall (*q.v.*), a turf wall stretching from Bo'ness on the Forth to Old Kilpatrick on the Clyde, with forts every few miles, a few of which still survive. The Romans also held a few sites north of the wall, notably at Ardoch in Perthshire, and a network of road posts and other forts along the main valleys which cut into the Southern Uplands. This elaborate system, however, proved to be ineffective, and toward the end of the 2nd century the Romans withdrew to Hadrian's Wall (*q.v.*), running from the River Tyne to the Solway Firth, which was reconstructed and remained as the chief defense of the frontier for another two centuries.

Apart from punitive expeditions by the emperor Lucius Septimius Severus in 209 to 211, the Roman armies did not return to Scotland; but they did not ignore it. In the 4th century *exploratores* ("scouts") appear to have been stationed in southern Scotland though not in any settled bases; while the Romans seem to have established some sort of formal relations with certain of the native tribes. Client kingdoms appeared with their headquarters at Dumbarton and in Lothian; and although the eastern kingdom of Manau disappeared in the disturbances of the 5th century, the western remained to become the Dark Age kingdom of Strathclyde.

Little information survives about events among the native peoples of Scotland. Increasingly Roman sources mention the Picts; and it may be that this people, unmentioned by Ptolemy, were during the Roman period establishing a powerful kingdom with its centre in Strathmore, but nothing is known of how this was done, or about the state or history of the rest of Scotland.

During the 6th century, two other peoples appeared in Scotland. The Anglians of Northumbria spread into the Tweed Valley, the Merse, and Lothian, perhaps into the void left by the disappearance of Manau, after its ruler Cunedag (Cunedda) was removed to North Wales in the 5th century. In the early 7th century, the victories of Aethelfrith, king of Northumbria, extended the power of that kingdom well into the county of Dumfries, where remain a number of important Anglian carved monuments, notably the Ruthwell Cross. Meanwhile in the west, about the middle of the 6th century, some of the "Scotti" from Ireland settled in Argyll and the islands off its coast, to form the kingdom of Dalriada.

2. The Conversion.—Very little is known for certain about early Christianity in Scotland. Numerous lives were written of particular saints, such as St. Ninian and St. Columba, as well as of many others less well known; but of these only Adamnan's "Life of Columba" (ed. by A. O. and M. O. Anderson, 1961) was composed within a century of the life of the saint. Most were written long after, and, while they probably include traditions of historical value, these are difficult to disentangle from the legends.

It is, however, certain that Christianity first came to Scotland through contacts with Roman civilization. St. Ninian is said to have visited Rome and Gaul before establishing his church at Whithorn, traditionally in 397 (but *see* NINIAN, SAINT). The earliest evidence of Christianity in Scotland is a small group of tombstones inscribed in Latin, with Christian formulas and sometimes the Chi-Rho monogram, which are found mainly at Whithorn and Kirkmadrine in Galloway, with a few scattered examples elsewhere in the south of the country. It was possibly in the kingdom of Strathclyde that St. Patrick received a Christian upbringing before he became the apostle of Ireland.

It is uncertain how far this sub-Roman Christianity survived into the Dark Ages. Tradition has always given the main credit for the conversion of Scotland to St. Columba who came from Ireland to settle in Iona (*c.* 563 or 565). From there he is said to have converted both the Scots and the Picts. Bede, however, (*Ecclesiastical History*, III, 4) seems to imply that St. Ninian had already converted some of the Picts; and church dedications to St. Ninian are much more widespread than one would expect if he had confined his work to Strathclyde and Galloway. In any case, it is clear from legends about and dedications to many other saints that the conversion of Scotland was not a simple process.

Even less is known about the history of the church in Scotland in the following centuries. It is usually assumed that an early age of fervour was followed by several centuries of decline. Scotland was remote from the rest of Europe and developed with little contact with European civilization. It was slow to adopt such changes as the new method of calculating the date of Easter, formally adopted in northern England at the Synod of Whitby (663 or 664); and St. Margaret, who came from Anglo-Saxon England during the 11th century, was impressed by the antiquated rituals and customs of the Scottish Church. On the other hand, the church was still in existence. There is evidence of this in a large collection of tombstones at Govan which belong to the 9th and 10th centuries; in many carved crosses and other monuments; and in many small oratories and cells, remains of which can still be found in the remoter parts. One cannot be more precise than this; but it is likely that the church founded by the early saints survived in some form through the troubled period of the 8th to the 12th centuries to become the foundation on which the medieval church in Scotland was erected. In some areas at least, the parish churches of the 12th century were on sites which had long been in religious use. The church of Govan, traditionally founded in the 6th century, was in the 12th century and is today the centre of a large parish.

3. The Establishment of the Kingdom.—Meanwhile the political condition of Scotland was becoming more simple. In the late 8th and 9th centuries, there were widespread Norse raids and settlements in the north and west of the country. Orkney and Shetland, Caithness and Sutherland, became Norse provinces, as did the Western Isles, which became part of a Norse "sphere of influence" including the Isle of Man and the eastern seaboard of Ireland.

These attacks seem to have led the other peoples in Scotland to draw together in face of the new invader. In the 9th century (traditionally in 843, perhaps in 844) Kenneth I MacAlpin (d. 858), king of the Scots, became king also of the Picts. In the 11th century, the royal line of Strathclyde died out, and that kingdom also came under the rule of the king of Scots; while the Scandinavian settlements had also weakened English power in the north and Scottish influence increased in Lothian. It is hard to be sure when it was finally incorporated in Scotland: it may have been conceded by the Anglo-Saxon king Edgar between 971 and 975, but the defeat by Malcolm II (1005–34) of the Northumbrians at the Battle of Carham in 1016 or 1018 is often treated as the decisive event.

By the 11th century, therefore, apart from the regions settled by the Scandinavians, all the areas of Scotland recognized the same king. This unity, however, was superficial and nominal. The provinces of Strathclyde and particularly Lothian were very different in people and in history from the northern parts of the country, and were much more open to southern influences. These divisions were to become very obvious in the late 11th and 12th centuries; but they appear to some extent in the obscure usurpation and reign of Macbeth (1040–57) who came from the Pictish area and was opposed and defeated by Malcolm III Canmore (1058–93) with English aid.

The Scottish kingdom had been created by the 11th century, but the work of consolidation remained.

B. THE CONSOLIDATION OF THE KINGDOM, 1058–1286

This consolidation was the main achievement of the dynasty of kings descended from Malcolm III Canmore and his English wife Margaret (*see* MARGARET, SAINT). With only a brief interval after the death of Malcolm III himself, the throne remained in his family until the death of Alexander III in 1286. In 1097, Malcolm's son Edgar (1097–1107) was placed on the throne with the help of William II of England; and he was succeeded in turn by his brothers Alexander I (1107–24) and David I (1124–53). David's son Henry died before him, but by then the hereditary succession had become sufficiently established for David to be succeeded by his grandson Malcolm IV (1153–65) and he, in turn, by his brother William the Lion (1165–1214). From 1165 till 1286, Scotland was ruled by only three kings, William himself, his son Alexander II (1214–49), and his son Alexander III (1249–86), who succeeded as a child of eight and reigned until his death in a riding accident.

During this period, the dynasty had many connections with England, beginning with Malcolm III's own exile there during the reign of Macbeth and his later marriage to Margaret, the sister of the English prince Edgar the Aetheling (*q.v.*). It was with William II that Malcolm's sons found refuge during their short exile after his death; Henry I of England married Edith, a daughter of Malcolm and Margaret; while Malcolm's son David married an English noblewoman, Matilda, countess of Huntingdon, in whose right he was, before he became king, earl of Huntingdon. After David I, connections with England were less close, though David's son Henry, William the Lion, Alexander II, and Alexander III all married English wives.

1. Administrative Developments.—It was natural, therefore, that these kings should introduce into Scotland many practices which they had met in England. From the late 11th or early 12th century, Scottish kings issued documents in Latin, whose form was very closely modeled on the Anglo-Norman "writ-charter," and from this model there developed in the 12th and 13th centuries a variety of types of document which were in general parallel to those being issued in England, though the precise formulas were often different. Again, the sheriff or vicecomes appears in the 12th century as the principal royal official of a sheriffdom or vicecomitatus. Although there were earlier local officials with various titles, the sheriffdoms and sheriffs of the 12th century seem to have been new creations, modeled on English practice. These and other officials, as in England, had to render account for their receipts and expenditure of royal revenues before a board of auditors appointed to hold sessions of the exchequer. The earliest evidence for this is in some accounts rendered in the years 1264 to 1266, and 1288 to 1290, a copy of each of which has survived; but all other Scottish royal records before the early 14th century have been lost and this makes it impossible to say just when this system was introduced. It was certainly not new in 1264; and was very probably the normal practice from the first introduction of sheriffs in the early 12th century. At the same time, too, as the sheriffdoms were established, royal castles appear, normally in the hands of the sheriffs, in the chief towns.

2. The Anglo-Norman Families.—As well as bringing these innovations from England, the kings, especially David I, Malcolm IV, and William the Lion, brought to Scotland members of many of the Norman families of England. During the reign of David I, the Bruce (*q.v.*) family was established in Annandale, the De Morvilles in Ayrshire and Lauderdale, and Walter son of Alan (*see* STEWART) was settled in Renfrewshire. These brought with them others, from their English estates, who were settled on parts of their Scottish lands; while throughout the 12th century many lesser men, whose families came originally from a wide area of

northern France, but most of whom had first been settled in England, were granted estates in Scotland. This introduced a new and foreign nobility who were most powerful in the southern part of the country; while the native nobility, with whom they intermarried, remained predominant in Lennox, Fife, Angus, and further north. Gradually, the two groups fused, until by the 13th century there seems to have been little distinction between them.

With these English or Norman nobles, the Scottish kings introduced the feudal system of landholding; these settlers commonly held their lands, as they would have in England or France, by the service of so many knights. The Bruces, for example, were granted Annandale for the service of ten knights. But this service was owed only where a specific grant demanded it; most established landowners continued to hold their estates by the same obligations as before, such as the payment of food-rents of various kinds, or the performance of services, including military service; so that by the end of the 12th century the kings were owed a bewildering variety of services and payments by the landowners of Scotland.

By the reign of William the Lion, therefore, the kings of Scots had established a system of government which followed closely the lines laid down in other areas of western Europe. The innovations, however, aroused opposition from some of the native nobles who resented the new methods and new men introduced to Scotland at this period. On the death (1093) of Malcolm Canmore, those hostile to the English influences were able to put on the throne two kings of a rival line, Malcolm's brother Donaldbane (1093–94 and 1094–97) and Duncan II (1094), son of Malcolm's first marriage, before Edgar, son of St. Margaret, was established with English help in 1097. There were risings in Argyll led by Somerled in the reign of Malcolm IV; and by descendants of Duncan II in the reigns of William the Lion and Alexander II.

3. Extent of the Kings' Territorial Authority.—Moreover, although the kings of the Canmore dynasty had consolidated their authority, it was only effective within limits much narrower than those of present-day Scotland. The main centres of the king's power lay in his estates in Angus, Fife, and the Lothians, and it was there that the kings spent most of their time. Those Norman settlers who were to be the leading members of the Scottish baronage were, for the most part, granted estates in regions where the king's own personal authority was less. The Stewards (Stewarts) in Renfrewshire (a counterbalance to the native family of the earls of Lennox across the Clyde), the De Morvilles in Ayrshire, the Bruces in Annandale, the De Soulis in Liddesdale were, in effect, the instruments of royal control in areas where the crown could less easily rule by its own authority. By such means, the kings were able, either directly or through the Norman nobles, to control most of Scotland south of the Highland line.

On the borders of this area, however, there were a number of regions where native powers remained strong. Galloway, Lennox, central Perthshire, Garioch in Aberdeenshire were all areas in which the king's power was uncertain. William the Lion had much trouble with Galloway, and it was not until 1234 that the last of the native line of lords of Galloway, Alan, died, leaving three heiresses who were all married to Norman barons and thus introduced Norman influences. Even so, the area remained of uncertain allegiance as late as the wars of the 14th century. William the Lion, too, tried to extend his power at the other end of the Highland line by making his brother David earl of Huntingdon, lord of Garioch. Further to the west and north, the islands as well as the mainland of Caithness and Sutherland remained in the hands of the Norse. William the Lion made an expedition to Caithness in 1196, in which he asserted his authority over the Norse settlers. Alexander II and Alexander III both campaigned in the Norse areas, as a result of which there occurred the celebrated Battle of Largs (1263); and these efforts resulted in 1266 in the treaty by which Magnus V Lagaboeter, king of Norway, surrendered to the king of Scots all Norse possessions in the Western Isles except Orkney and Shetland.

Thus, by 1266, the kings were in theory masters of the whole mainland of Scotland; but this control was nominal in the bulk of the central Highlands, and still more so in the areas ceded by the Norse. The Western Isles in particular remained for all practical purposes independent; and under the Macdonalds, who later became lords of the Isles, acted as a separate power which entered into independent relations with England at various points during the wars of the 14th and 15th centuries.

4. Growth of the Church.—The kings, however, did not confine their innovations to the government of Scotland: they also made great changes in the church, which in St. Margaret's day (11th century) had fallen out of touch with many of the developments which had occurred in the Western Church. There were bishops, but, perhaps naturally in the still loosely organized political state of the country, no sign, so far as the evidence goes, of a clearly organized diocesan system. There seem to have been monks of a sort, or at least groups of clergy living together; some of which, mainly those in the Pictish parts of the country, are known to tradition as "Culdees" (*q.v.*) though there seems to be little difference between these and groups in other parts of the country, as at Govan, which are not so called; but regular monasticism according to the rule of St. Benedict was unknown.

The rule seems to have been introduced to Scotland by St. Margaret herself in her foundation at Dunfermline; but elsewhere in Europe many new religious orders were being founded; and, since regular monasticism was introduced so late to Scotland, it was natural that strictly Benedictine houses should be comparatively rare. Alexander I founded two houses of Augustinian Canons, at Scone and Inchcolm, while David I made foundations of the reformed orders, such as the Cistercian houses of Melrose and Newbattle, the Tironensian (from Tiron, in Picardy) house of Kelso, and the Augustinian house of Cambuskenneth. By the end of David I's reign Scotland, from being almost devoid of monasticism, was rich in houses.

The founding of monasteries, however, was expensive: it required large areas of land with which to endow the new house; and it was at first only the kings who were able to indulge in it. Therefore, the majority of Scottish houses were established in the areas where the kings themselves possessed great lands—Angus, Fife, the Lothians, and the Tweed Valley; and it is often suggested, following a comment attributed to James I that his predecessor was a "sair sanct for the crown," that David I's generosity to the church seriously impoverished the crown. This was probably not a fair comment, since signs of this impoverishment do not appear till much later, perhaps not even till the early 15th century when most European monarchs were finding themselves hard pressed for money; and for a long time David and his successors got a very good return for their investment in the form of services of all kinds performed by churchmen in the royal administration, both local and central.

Few of the nobles could afford to follow suit. There were a few important houses founded by Norman settlers, notably Dryburgh (Premonstratensian Canons) founded by Hugh de Morville in 1150, and Paisley (Cluniac) founded by Walter son of Alan (founder of the Stewart family) about 1163; but most baronial foundations were late and small. Hardly any of the native nobility founded houses of importance, unless, as is probable, the abbey of Dundrennan (Cistercian), founded about 1140, was a foundation of Fergus of Galloway. The establishment of monasteries was almost entirely an activity of the foreign-minded kings and their foreign associates.

During the 12th century also the organization of the church kept pace with developments in the secular administration of the country. As the state became organized into sheriffdoms, so the church developed a much more regular diocesan system. By 1128, there is record of bishops of St. Andrews, Glasgow, Dunkeld, Moray, and Ross; by the end of the 12th century most of the dioceses of the medieval Scottish Church were already in existence, and there is an increasing amount of evidence of the development of cathedral chapters, who were gaining the right, formally at least, to elect the bishops, and of lesser units such as archdeaconries. It is also clear that parish churches were being more regularly established and brought under the control of the bishops. Unfortunately, a very large proportion of these were "appropriated" to monastic houses in the first enthusiasm for the regular

orders; this meant that the house drew the income of the church and became responsible for maintaining its services, which it usually did by appointing a lowly paid vicar. It was not until the 13th century (as a result of the decrees of the Lateran Council of 1215) that the bishops began to make attempts to regulate the appointment of these vicars and to fix minimum stipends which they had to be paid, often in the face of violent protestations of poverty from the monastic houses. Episcopal oversight, however, was often not effective, and the problem remained until the Reformation.

5. Cultural and Economic Developments.—It might be expected that along with these developments in the church would go advances in culture and learning. No doubt these followed, but little evidence has remained. Scotland in this period produced only two monastic chronicles which have survived, the chronicles of Melrose and Holyrood: these are brief sets of annals and, although they have great historical value, they are not works of literary importance. Nor is there much evidence of manuscripts being copied or illuminated in Scotland. Attached to the monasteries were often schools; but, apart from occasional references to schoolmasters, nothing is known of their work. Scotland produced in the period one theologian of note, Adam Scotus (fl. late 12th century). There is, however, some evidence of architecture at the time which suggests that Scotland was in touch with work being done elsewhere. Fine, if small, Romanesque churches survive at both Dalmeny and Leuchars; the nave of Dunfermline Abbey is closely modeled on that at Durham; the ruins of St. Andrews Cathedral make it obvious that it was originally a fine Romanesque building; and Elgin, and particularly Glasgow, cathedrals are 13th-century churches which, though smaller, are worthy to be compared with English work of the same period. In Orkney, Kirkwall Cathedral is an example of a 12th-century church in a more primitive style.

Fewer examples of secular architecture remain: most castles were probably built of wood on natural or artificial mounds; but 13th-century work survives at Bothwell and Dirleton which seems again to compare well with English work of the period; and there are a number of 12th- and 13th-century castles in the county of Argyll and the Western Isles which, though rather more primitive in workmanship, are still notable examples of Medieval military engineering.

Contacts with England and the Continent brought new opportunities for trade; and the kings seem to have encouraged this. They deliberately founded burghs, either by creating new settlements or by conferring special privileges on existing ones. These were communities of merchants and craftsmen, though they engaged also in agriculture, which possessed a monopoly of the markets over a specified area; all buying and selling in the area had to take place in their market; and their merchants often enjoyed privileges of freedom from tolls throughout the country. Some burghs remained merely the local market; but others, particularly those with harbours, became important centres of trade. The earliest burghs recorded, which existed already in 1124, were Edinburgh, Stirling, Berwick, and Roxburgh, all in the southeastern part of the country; but many more were created, either by kings, bishops, or barons, in the 12th and 13th centuries, till they formed a network over most of the Lowland parts of the country; and foreigners were often encouraged to settle in them. No accounts survive of the extent of Scottish trade at this period, but Scottish merchants are recorded commonly enough in England; they had a wool staple in the Low Countries and traded also with Norway.

The introduction of monasteries had also some economic effects. The Border abbeys in particular developed the agriculture of the Tweed Valley; the abbey of Newbattle engaged in some coal mining; and the abbeys were normally linked to the commercial classes by having "tofts" or town houses in many of the burghs. Again, however, there is little evidence since the records which survive of the abbeys are mainly titles to their lands, and not accounts of the economic exploitation of their estates.

The impression left by the evidence is that Scotland in the 13th century was a reasonably flourishing land, though it is difficult to document this.

C. The Wars of Independence

The death of Alexander III in 1286 made immediate a problem which had been recurrent but only occasionally important during the previous two centuries: the precise relation of the Scottish crown to that of England. Twice, it seems, the kings of Scots had accepted English overlordship, once when Edgar was established by William II, and once when William the Lion, who had joined in the rebellion of Henry II's sons, was captured at Alnwick in 1174. Henry II's gains of 1174 were surrendered by Richard I in 1189 in return for money, but this left unresolved the question whether the kings of England were entitled to a general overlordship apart from that which Henry II had won as a result of the capture of William the Lion. There were remote precedents, particularly a submission by various kings to Edward the Elder in 920; and the issue was complicated by the fact that Scottish kings held lands in England for which, as English barons, they undoubtedly owed homage to the king of England. On the other hand, there was no question that Scotland was admitted to be a kingdom, albeit a kingdom with some defects of form, especially that the kings of Scots were neither crowned nor anointed. The inauguration of the Scottish kings was purely a secular ceremony, a placing on the royal seat (the "Stone of Destiny"), not an ecclesiastical consecration. In the 13th century, the Scottish kings made various attempts to gain from the pope the right to coronation and unction; but these efforts were circumvented by the English government, which was anxious to maintain any signs that the Scottish kings were not kings in the fullest possible sense. The question remained unresolved: Alexander III performed homage (1278), but, according to one version of his oath, claimed that he did it only for his English lands and saving the rights of his kingdom, while the English similarly saved the rights of their king.

1. The Disputed Succession.—In 1286, the problem became immediate. Since Alexander III's son Prince Alexander had died in 1284, the only heir was Margaret the "Maid of Norway," the young daughter of Alexander's daughter Margaret who had married Eric II, king of Norway. To her, the Scottish barons had sworn allegiance in 1284. To maintain the government till she could come to Scotland and was of an age to reign, a group of barons were appointed "guardians." For the next five years they were responsible for the welfare of the state.

Edward I made no immediate attempt to profit from the situation, and it is not likely that at this stage he had any definite aim to exploit his position as overlord. In 1289 he made the proposal that his son Edward should marry the Maid of Norway and, in course of time, rule over both kingdoms: this idea met no serious opposition. It was accepted by the guardians at the Treaty of Birgham (July 1290, confirmed by Edward in August), which, however, made elaborate provisions for the preservation of the integrity of the kingdom of Scotland, which was not to be incorporated with England but ruled as a separate realm. The plan failed, however, with the death of Margaret in Orkney in September 1290. There was now no clear heir to the throne.

The two most serious claimants were Robert de Bruce (1210–95), "the Competitor," and John de Balliol (*q.v.*); both were descended from daughters of David earl of Huntingdon, the brother of William the Lion. There were, in all, 11 other claimants, but no others seem to have been regarded seriously except, perhaps, Florence count of Holland, who was descended from a sister of David. Bruce and Balliol were each supported by strong groups of the Scottish nobility, and there were rumours of preparations for war. In this situation, it was natural to turn to Edward I and ask him to arbitrate, as he had done, for instance, in a similar dispute over the succession to Castile.

2. John de Balliol.—Edward, however, refused to act on this basis. He asserted that he was superior lord of Scotland; that the kingdom was a fief which reverted to its superior who was entitled not to arbitrate but to judge the issue. Not till all the competitors accepted these claims, and until the kingdom had been formally placed in his hands, would he act. He then assembled a court which, after long examination, pronounced in 1292 in favour of John de Balliol, as descended from the eldest of David earl of Huntingdon's three daughters. Balliol was therefore enthroned

but required to perform homage explicitly for the kingdom of Scotland and to admit Edward's rights as superior lord.

During the reign of John de Balliol (1292–96), Edward insisted on exercising these rights by hearing appeals against the judgments of Balliol's court, by summoning Balliol to answer before his own court, and, eventually, by summoning Balliol and the Scottish barons to do service in his wars in France. Balliol was unable to resist effectively; but the last demand provoked the opposition of the Scottish barons, who, in 1295, set up a commission of bishops, earls, and barons to conduct the government of the country on behalf of Balliol. These allied with Edward's enemy, Philip IV of France, and Edward retaliated by treating Balliol and the Scots as contumacious vassals. In 1296 he invaded Scotland, captured Berwick and Dunbar, forced the resignation of Balliol, and took the government of Scotland into his own hands.

Revolt, however, was soon raised, partly ineffectively by a group of barons which included Robert Bruce, grandson of the "Competitor," and future king Robert I (1306–29); and more effectively by William Wallace (*q.v.*) and Sir Andrew Moray. Wallace and Moray defeated the English armies at Stirling Bridge (1297), shortly after which Moray died; and Wallace was appointed sole guardian on behalf of the exiled John de Balliol, whose resignation was regarded as invalid and in whose name government was now carried on. Edward, however, defeated Wallace at Falkirk (1298); but found that he was now committed to the military conquest of Scotland. A series of campaigns more or less reduced Scotland to subjection, though at enormous cost in effort and money, and Edward seemed triumphant when in 1305 Wallace was captured and executed as a traitor.

3. Robert I the Bruce.—In 1306, however, Robert Bruce decided to revolt, and, after his murder of John Comyn (*q.v.*), a possible rival, at Dumfries, was crowned king at Scone in March 1306 (he had to be crowned, since the "Stone of Destiny" had been removed by Edward). At first he had little success (*see* ROBERT I); but Edward I died in 1307 and his son Edward II was incapable of waging the sort of war which had placed Edward in control of Scotland. Bruce had the support of a number of notable Scots, especially Walter the 6th Steward, James Douglas ("the Good"), and his own nephew Thomas Randolph, the future earl of Moray; and as he became more successful others joined him. By 1314 almost all the English castles in Scotland had been captured, except for Berwick and Stirling; it was Edward II's attempt to relieve the latter which led to the decisive Battle of Bannockburn (*q.v.*). With the fall of Stirling, followed by the capture of Berwick in 1318, the English had lost all their strongholds in Scotland.

The war was prolonged by Edward II's refusal to recognize Bruce's position. The Scots invaded the north of England several times; but for most of the time there was an uneasy truce during which the Scots made determined efforts to secure recognition of their independence, especially from the papacy. Eventually the government of Isabella and Mortimer, during the minority (1327–30) of Edward III, conceded what was needed, by a treaty drawn up at Edinburgh and confirmed at Northampton in 1328. The English were now prepared to recognize Bruce as king of Scots; and his triumph was sealed by a papal bull which granted the long-sought rights of coronation and unction. It was issued six days after the death of Bruce himself in 1329; and the first Scottish king to be crowned and anointed with the full rites of the church was his young son, David II (1329–71), in 1331.

4. David II.—The treaty of 1328 did not, however, put an end to the Wars of Independence: Bruce's death and the succession of his young son at the age of five gave the English an opportunity to renew their claims. The attack began in 1332 as an attempt by Edward de Balliol, the son of John de Balliol, to seize the throne with the help of a number of English nobles who had lost lands in Scotland. They won the Battle of Dupplin (*q.v.*) in August, and Balliol was crowned at Scone (September) but after a defeat in December fled to England. Edward III now gave him open support (*see* BALLIOL) and in 1333 defeated the Scots at the Battle of Halidon Hill (*q.v.*) just outside Berwick, captured Berwick itself, and went on to overrun much of Lowland Scotland. Edward de Balliol was restored, did homage to Edward for the kingdom, and, as a reward for his aid, ceded most of Scotland south of the Forth into English hands. David II was soon forced to flee to France (1334). The southern counties were now organized under an English administration with English sheriffs centred on Berwick-on-Tweed. In the rest of the country there were English garrisons holding castles for Edward de Balliol. It seems that none of these had much control outside the immediate areas of their garrisons; but the Scottish administration collapsed and does not seem to have revived for some five years.

Scotland, however, was by no means conquered. Resistance remained in the north, under Andrew Moray, a son of the elder Andrew Moray; and in the west under Robert the 7th Steward, son of Walter the Steward and Bruce's daughter Marjory, who was heir to the throne in default of direct issue to David II. In the following years there were several English invasions; but the Scottish leaders gradually recovered more and more territory. By 1340, the customs were again being collected, though at first only in the northeast; by 1341, David II was able to return to Scotland; and by 1342 English bases in Scotland were reduced to Berwick and Lochmaben.

Once again the kingdom seemed secure; but David II was captured at the Battle of Neville's Cross (1346) near Durham during an attempt to invade England, and remained in captivity till 1357. The English recovered some of the south and had to be slowly ejected by the Steward and William lord (later 1st earl) of Douglas (a nephew of Sir James Douglas). In 1356, English control was reduced to Berwick and Roxburgh in the east, and Lochmaben with lower Annandale in the west. An English expedition in that year achieved little; and in 1357 Edward agreed to release David II for a large ransom. It was not till 1384 that the Scots recovered Lochmaben; not till 1460 that they gained Roxburgh; Berwick, however, after being gained by the Scots in 1461 was finally taken by Richard duke of Gloucester in 1482 and has remained English ever since.

D. THE CONSEQUENCES OF THE WARS, 1329–1424

This long-continued struggle with England was in many ways disastrous for Scotland. The material damage caused by English attacks and by Scottish counterattacks on English-held positions was considerable; so much so that few buildings survive from before the period of the wars, especially in the south of the country. Moreover, building done in the late 14th century is often conspicuously inferior to what does remain of 13th-century work; and the surviving records of monasteries often suggest that the first half of the 14th century was a period of economic hardship. The war also involved the kings in heavy expenditure, for campaigns or to pay David II's ransom; this in turn led to great increases in taxation, especially immediately after David II's release, when the rate of the normal wool taxes was trebled and finally quadrupled.

The most serious consequences of the wars, however, were upon the position of the kings. Robert Bruce seemed by his death to have established himself with all the traditional authority of the kings of Scots; but it was long before his son enjoyed an equally secure position. Edward de Balliol existed as a rival, claiming himself to be the lawful king. Except for a short time in the 1330s, few Scottish nobles supported him; but he was there as a possible alternative to whom dissidents could turn, and a few, particularly in the far west and southwest, made a point of professing their allegiance to him. The uncertain position of David II encouraged areas not effectively under royal control to disregard it completely.

Further, King David's minority with the troubles of that time, shortly followed by his captivity, resulted in two periods in which central government ceased almost entirely to function for, together, something like 17 years. Although David made strenuous and effective efforts to regain royal control in the 1360s, he died before he could establish a tradition of strong government; neither Robert II (1371–90) nor Robert III (1390–1406) were men capable of asserting their authority effectively; while James I (1406–37) spent the first 18 years of his reign as a captive in England,

leaving Scotland to be governed in his absence by his uncle, Robert Stewart, duke of Albany, who used his considerable authority to establish his own position and that of his family rather than to restore strong central government. Thus, between 1329 and 1424, there were probably only two short periods, from 1341 to 1346, and from 1357 to 1371, in which the authority of the crown was effective.

1. Baronial Aggrandisement.—Meanwhile, the wars with England had produced important changes in the Scottish baronage. The leading supporters of Robert Bruce, particularly Sir James Douglas and his half brother Sir Archibald (*see* DOUGLAS) and Thomas Randolph, 1st earl of Moray (*q.v.*), received great grants. James Douglas got the previously royal forest of Selkirk and many other lands in the upper Tweed and elsewhere; Archibald Douglas received lands in the southwest; while Randolph got Annandale, Moray, and the Isle of Man, though he never gained effective control of the last. These grants were the natural reward for the king's most faithful supporters: Bruce could not do better than entrust the defense of these lands, many of them very open to attack, to the men who had won them from the English. The policy seemed all the sounder in that these were men whose personal loyalty to the king was beyond doubt.

Nevertheless, these grants had changed the whole balance of power in the kingdom by depriving the crown of direct control of much of the south of Scotland, which grew into something approaching a personal lordship for the Douglases. Sir James died in 1330, a year after the king; and this broke the personal link which had been the justification of Robert Bruce's action. In the course of the 14th century, several of the separate lordships in Douglas hands were united by a natural process of inheritance until, by the early 15th century, virtually the whole of southern Scotland from the middle Tweed Valley to Galloway was held by the earls of Douglas, who had achieved a power far stronger than could safely be entrusted to a subject. Within this area, the king exercised little direct control, and even less in practice than he reserved in theory; while the situation was made worse by the lawlessness natural in a border country under constant threat of raiding. The weakness of the crown was accentuated by the enormous power held by a nominal subject in a vital area.

2. Parliament.—One development, however, was helped indirectly by the troubles of the period, that of the Scots Parliament. There is no doubt that the kings in the 13th century had held assemblies of their subjects: the meeting to swear allegiance to the Maid of Norway in 1284 is an example, as are various assemblies in the 1290s. These were predominantly gatherings of the nobles; though it is likely that representatives of the burghs attended on occasion. As in England, however, it was the need to raise money which allowed the burghs to establish their position in Parliament. We first hear of burgh representatives in 1326, when Robert Bruce required money; and the rights of Parliament and of the burgh communities in particular were further strengthened during the 1360s when additional taxation was needed to pay the ransom of David II. Nevertheless, the Scots Parliament never attained the influence or prestige of that of England (*see* also PARLIAMENT: *The Parliament of Scotland*).

E. The Revival of the Monarchy, 1424–88

In the 15th century the kings made serious efforts to restore effective government, particularly to reduce the power of the greatest barons. When James I returned from his captivity in 1424 he found Scotland dominated by the family of the late regent Albany (d. 1420). Albany's son Murdac had succeeded him as regent, and other members of the family had gained great power in various parts of the country. One of King James' first acts was to arrest as many of these as he could, along with many other nobles, most of whom were soon released after this assertion of royal authority had produced its effect. Murdac, however, and his two sons were executed (1425) on obscure charges.

Now that the king's cousins, descended from Robert III's brother Robert, duke of Albany, had been disposed of, the other great baronial power was that of the house of Douglas. Ever since the reign of David II, the family had been growing still more powerful. During the regency of Albany, there is evidence in the exchequer rolls that members of the family could with impunity seize some of the customs revenue; and no attempt was made to stop their depredations or to bring them to order. James I seems to have avoided any direct clash; but his successor James II (1437–60) resorted to violence. William, 6th earl of Douglas, and his brother David were executed for alleged treason in 1440 during the king's minority. William, the 8th earl, was murdered by the king himself in 1452; and James, the last earl of Douglas, was detected in treasonable communication with England and driven into exile in 1455. He spent the rest of his life in England, from which he planned rebellions against James II and James III. Thus the power of the main line of the earls of Douglas was destroyed; though a cadet branch, the earls of Angus, remained loyal and were to become very strong in the latter part of the 15th century.

During the 15th century, too, the kings made a number of efforts to extend their effective control into the remoter parts of the country. James I made several expeditions to the north and west; but the line of the lords of the Isles, who now claimed also the earldom of Ross by marriage, remained hard to control and liable to take the law into their own hands by plundering the territories of other magnates in their area. They were the more dangerous in that they could hope to exploit English hostility to the kings of Scots. In 1462, acting as an independent authority, John MacDonald, lord of the Isles and earl of Ross, made the strange Treaty of Westminster-Ardtornish with Edward IV of England, by which they planned, with the exiled James, earl of Douglas, the partition of Scotland. Nothing came of this; and the power of the lord of the Isles was crushed after a rebellion in 1475. James III (1460–88) deprived him of the earldom of Ross, and, although he was confirmed in the title of lord of the Isles, his effective authority was severely restricted.

James III also gained finally for Scotland the two remaining groups of islands still subject to Norse control, Orkney and Shetland. These were pledged (Orkney in 1468, Shetland in 1469) by Denmark for the payment of the dowry of the queen, Margaret of Denmark, whom James married in 1469; as the dowry was never paid, the islands were formally annexed by Parliament in 1472.

1. Administrative Improvements.—During James I's captivity in England, he had learned much about English methods of government; and on his return to Scotland he tried to remodel Scottish government on similar lines. In particular, he made far greater use of Parliament than his predecessors as an instrument to introduce reforming legislation, though, like most medieval legislation, much of it had probably little effect. It is in this reign that the continuous records of the Scottish Parliament begin.

He was also impressed by the ways in which the English king's finances were organized. From the exchequer rolls, it appears that the income of the Scottish crown had been declining during the period since 1371. Further, such control as there was of the king's resources remained in the hands of the chamberlain, to whom were paid all revenues which were not at once spent locally by their collectors, on the king's warrant. This placed far too much financial power in the hands of a household official whose office had become, under the Stewart kings, a position of dignity held since 1382 first by Robert Stewart, the future duke of Albany, and since 1407 by his son John, earl of Buchan. James was probably concerned to reduce the power of an office which had become associated with the family of Albany; and he achieved this by introducing two new financial officials, who soon effectively superseded the chamberlain. The latter remained an office of some dignity, but its financial authority was gone. Routine revenues, of crown lands, customs, and the like, were to be handled by the comptroller; while extraordinary revenues and the general management of finance were given, on the English model, to the treasurer. Both these officials were working civil servants, not magnates. Thus James gained a much more effective and direct control of his revenue.

2. The Period of Minorities.—The revival of royal authority in the 15th century was real, but its effects were limited. James

I had removed the rival house of Albany; but there remained that of Atholl, descended from the second marriage of Robert II, and anxious to maintain that that king's first marriage, from which the later Stewart kings were descended, was invalid. This claim must have been the basis of the obscure conspiracy which resulted in the king's murder at Perth in 1437.

There was no general support for the conspirators, who were all captured and executed; but James II succeeded as a child of 6; and was in turn killed at the age of 29 during the siege of Roxburgh in 1460, leaving as his heir James III, aged 8. As a result, something like half of the period between 1406 and 1488 was a time in which the power and influence of government were in the hands of those who could seize the king or wield power in his name. In the late 14th century, some semblance of order had been preserved by Albany and Douglas, who were prepared to work together; but the earls of Douglas in the 15th century were not concerned to uphold authority. As a result, during the minority of James II, control of the king was disputed by the families of Crichton and Livingstone, amid a general collapse of authority; while in the 1460s the young James III came under the influence of the Boyds of Kilmarnock, whose leader Robert gained for his son the title of earl of Arran and the hand of the king's sister (1467).

Jealousy produced a reaction, and Arran and his father only escaped execution by exile in 1469. James III himself offended some of his nobles by his friendship for artists, architects, and musicians; a group revolted in 1482, in face of an English invasion, and hanged several of the king's favourites over the bridge at Lauder; and then revolted again in 1488, with the help of the king's son James, duke of Rothesay. The result was the Battle of Sauchieburn, after which James III was killed while fleeing from the field.

The repeated troubles and insurrections of the period made it difficult for the kings to assert effective control over their kingdom, and the exchequer rolls continue to give evidence of such defiance of authority as the plundering of the customs revenue by families of local power. The result, despite the efforts of the kings, was that Scotland remained a state in which great power was vested in the landed nobility. The great families of the later 15th century, the Douglas earls of Angus and the Hamiltons, together with others of more local power such as Hume and Hepburn in the borders, Kennedy in the southwest, Gordon in the northeast, could not effectively be brought to account by the crown and could only too easily take the law into their own hands when it pleased them. Their power and influence survived into the 16th century when it was to dominate the political and religious struggles of that time.

3. Scotland in the 15th Century.—Despite the wars with England, the difficulties of the Scottish government, and the internal disturbances, there is evidence that in Scotland the 15th century was a period of economic revival and development, after the more difficult times of much of the 14th century. From the late 14th century, the nobility were engaged in building on a much larger scale than before; spacious and impressive halls, as at Bothwell and Dirleton, were built, often with no regard for defense. In the church, too, the 15th century was an age when monasteries and cathedrals were much rebuilt or extended. From about the middle of the 15th century, many monasteries seem to have reorganized the leasing of their estates in a more businesslike way; numerous rentals and registers of leases survive, almost all dating from this period. Hardly any survive from before 1450. It is hard to produce statistics of trade, but there is perhaps evidence of the prosperity of the towns in the rich foundations of collegiate churches made in Stirling and Edinburgh in this period. Scotland in the late 15th century seems to have been much more prosperous than in the dark days of the 14th century.

Of culture, it is more difficult to speak. By the end of the 15th century, Scotland had three universities—St. Andrews, founded in 1410 (papal bull, 1413) and strengthened by Bishop Kennedy's College of St. Salvator in 1450; Glasgow, founded by Bishop William Turnbull in 1451; and Aberdeen, founded by Bishop William Elphinstone in 1494. Some of the teachers, such as the first rector at St. Andrews, Laurence of Lindores, were men of note; but no Scottish-trained scholar achieved international importance until the 16th century. From the late 14th century onward, Scottish writings began to be of significance. John Barbour (*q.v.*) wrote in Scots a metrical life of Robert Bruce; John of Fordun (*q.v.*) wrote in Latin the first full-scale history of Scotland, though, unfortunately, his completed version did not go beyond the 13th century, and for the 14th century there are only brief annals. His work was extended and continued by Walter Bower (*q.v.*), abbot of Inchcolm, in the 15th century, to form his *Scotichronicon;* and Andrew of Wyntoun (*q.v.*) wrote in the early 15th century a metrical history in Scots, largely based on Fordun. (For further details of vernacular literature in the 15th century, *see* ENGLISH LITERATURE: *From Chaucer to the Renaissance;* SCOTTISH LITERATURE.)

Of art there is little evidence. One of the manuscripts of Bower's *Scotichronicon* is illustrated with some striking drawings; and fragments remain of wall paintings of uncertain date and quality. All that can be said is that Scotland was not out of touch with 15th-century continental work, since James III's foundation in Edinburgh, the collegiate Church of Holy Trinity, had a painted altarpiece (two wings of which are in the National Gallery of Scotland) with portraits of the king and queen, which came from the workshop of Hugo van der Goes. Most of the remains of Scottish art in the Middle Ages perished in the years between the Reformation and the revival of antiquarian interests in the 19th century. The main evidence remaining is the buildings of the period, which do not suggest that the country was lacking in artistic achievement.

F. THE SCOTTISH CHURCH AND THE PAPACY

Since the 12th century, the Scottish Church had been in a peculiar relationship with the papacy. Since there was no archbishop in Scotland, the two nearest primates, the archbishops of York and Canterbury, had disputed the authority over the Scottish Church, which was claimed by York at least since the 11th century, when its archbishops had consecrated bishops of Glasgow. Canterbury was anxious to prevent any gain in influence by its rival and claimed that the Scottish sees were subject to it; and the claim gained colour from the personal friendship of Lanfranc of Canterbury (1070–89) and St. Margaret. The majority of the Scottish bishops, however, resisted both claims; their independence of outside jurisdiction was first recognized by the papacy in 1164 and confirmed in 1192 in a bull which described the Scottish Church as "filia specialis" (special daughter) of the papal see. From the early 13th century, the right of the Scottish Church to hold councils although they had no metropolitan was expressly recognized; and this remained the situation until 1472, when St. Andrews was erected into an archbishopric, followed in 1492 by Glasgow.

Thus in the 12th and 13th centuries, the Scottish Church had turned to the papacy as its defender against claims from York and Canterbury. From the end of the 13th century, however, the Scots lost the political support of the papacy, and, as elsewhere, there developed opposition to its financial claims. At first, indeed, Pope Boniface VIII (1294–1303) supported the Scots in their struggle against Edward I; but Robert Bruce found it more difficult to get papal approval because of his sacrilegious murder of John Comyn. Although the Scottish Church supported Bruce, it was not till 1328 that the sentences of excommunication pronounced against him in 1318 for infringing a papal truce were formally lifted. The papal schism in 1378 also affected the relations of the Scots to the papacy. Being allied to France and opposed to England, they recognized the Avignonese pope Clement VII rather than Urban VI; and in fact continued their loyalty to the Avignonese popes long after these had been deserted by France and almost all other supporters. The Scots were the last to abandon the antipope Benedict XIII, about 1418. In the meantime, all papal confirmations and provisions in Scotland had been made by Benedict XIII; this meant there was the opportunity to dispute many of these when Scotland did recognize Martin V, the pope elected (1417) by the Council of Constance, and the resulting confusion persisted for some time.

When James I returned to Scotland in 1424 he was short of money, both to pay his ransom and for the needs of his government, so naturally he objected to the heavy financial demands made by the papacy, particularly in the form of payments on appointment to benefices and offices. The whole system of payments was linked with the system of "provisions" or papal appointments to vacant offices; which both reduced the royal authority over the church and deprived local patrons of their rights. James therefore in his early Parliaments introduced a number of laws aimed at reducing papal control over appointments and at preventing the payment of moneys to Rome.

James found the Scottish Church, which had no particular loyalty to Martin V, sympathetic to his aims. In the church at large, many thinkers at the time were critical of the papacy and anxious to subordinate papal authority to the control of general councils of the church. These "conciliarist" ideas had been very common in the University of Paris at the end of the 14th century; and many Scottish churchmen had been educated there. Hence there were many conciliarists in the Scottish Church, who took their part in the movement, particularly at the later Councils of Siena (1423–24) and Basel (1431–49). From these James could count on support for his attacks on papal influence.

James also approved of conciliar demands for reform in the church. He addressed letters to the abbots of Benedictine and Augustinian houses, calling for improvements; he introduced into Scotland the Carthusians, the strictest of monastic orders, and endowed the house which he established for them at Perth. There is, however, something backward looking in this concern for monasticism; he could do little to meet the real need of the church in the 15th century, the improvement of the status and education of the parish priests.

With James' death and the accession of his six-year-old son James II, his resistance to papal demands was abandoned. It was not a policy which could be carried on in the disturbed conditions of a minority; and the conciliar movement was in any case evidently waning. His successors found it more advantageous to work with the papacy and thus through papal provisions to secure the appointments they wished. The result was that over the century ecclesiastical office became more and more a means of providing for the king's relatives and the relatives of the nobility. Not all appointments made by these means were bad. In Bishops James Kennedy (d. 1465) of St. Andrews, William Elphinstone (d. 1514) of Aberdeen, and, even on the eve of the Reformation, in Archbishop John Hamilton (d. 1571) of St. Andrews, the church had men who could do their duties well, however they gained their offices; but the general scene was not edifying and many appointments were flagrantly scandalous. (Br. W.)

G. Scotland, England, and France, 1488–1567

1. James IV and V.—James IV (1488–1513) was all that his times thought kings should be—physically impressive, active and warlike, vigorous in dispensing justice, cultured, and open-handed. Only retrospectively did his mercurial nature and his impulsiveness in battle seem great faults. He took by forfeiture the lands and title of the last lord of the Isles in 1493, extended royal administration north and west, and acted against border lawbreakers. At a time when the "New Learning" was spreading through Europe, James and Bishop Elphinstone of Aberdeen founded King's College, Aberdeen. Elphinstone probably inspired an act of 1496, designed to provide a general and legal training for the children of the governing classes. James licensed Scotland's first printers, Walter Chepman and Andrew Myllar, in 1507. Some of Scotland's greatest poets profited from court patronage: Robert Henryson, whose *Testament of Cresseid* is notable for its compassion, was simply a burgh schoolmaster; but Gavin Douglas, bishop of Dunkeld and author of a superb verse translation of the *Aeneid,* owed his preferment to his relationship to the earls of Angus; and William Dunbar, writing in magnificent latinate Scots and with consummate technical mastery, could only have been the product of a court circle.

After initial disharmony with England, James concluded a "treaty of perpetual peace" with Henry VII in 1502 and married Margaret, Henry's daughter, in 1503. James's ambition to lead a European crusade against the Turks was doomed when even the pope, Julius II, engaged in divisive power-politics and in 1511 formed the Holy League to counteract French ambitions. England joined the League; whereupon France and Scotland, both wary of Henry VIII, renewed their "auld alliance" in 1512. When Henry invaded France in 1513 James's decision to uphold his alliance by invading England, and his rash generalship in the field, led to his death and that of the flower of the Scots army at the Battle of Flodden (September 1513).

James's firm rule at home, and his international ambitions, had required great expenditure on artillery, on a navy whose greatest ship, the "Michael," cost more than £30,000, and on embassies. The crown began to feu lands, that is, give heritable possession of them in return for a large initial payment and a fixed annual money-rent thereafter. This yielded ready money but ultimately reduced royal resources during the great Europe-wide price rise which went on throughout the 16th century.

At his father's death James IV had been 15 years old: James IV's son, when he became James V (1513–42), was only in his second year. During his minority, family and personal feuds revived; furthermore, a political division became increasingly clear, between those who supported the "auld alliance" and those who drew from Flodden the moral that Anglo-Scottish antagonism benefited only France. John Stewart, duke of Albany, a grandson of James II but by residence and upbringing really a Frenchman, was regent until 1524, and French interests prevailed. Archibald Douglas, earl of Angus, who dominated the young king for the following four years, favoured England. When James began his personal rule, with a treasury drained during his minority, he found a peculiarly favourable international situation: France, the emperor Charles V, England, and Pope Clement VII all vied for Scottish support, and James played on their conflicting interests. From the pope he obtained financial concessions as the price of his continued allegiance to Rome and, after considering many brides, he made two successive French marriages, each bringing a large dowry. His first wife, Madeleine, daughter of Francis I, died shortly after their marriage in 1537, and in 1538 he married Mary, daughter of Claude de Lorraine, duc de Guise. Some of the nobles disliked James's adherence to the pope and to France; others suffered from his brutal suppression of Highland and border lawlessness, and from his acquisitiveness. The low morale of the Scots led to the humiliating defeat of a force invading England, at Solway Moss in November 1542. This disaster, added to the deaths of his infant sons, crushed James, who died in December, a week after the birth of his daughter and successor Mary (1542–67).

2. State of the Church.—It would be rash to assert that clerical immorality and ignorance were worse in 16th-century Scotland than in other lands or at other times. But the church was top-heavy with wealth, and poor and ineffective in its witness before ordinary people: by 1560 the bulk of the revenues of nearly nine-tenths of the parishes was appropriated to monasteries, cathedrals, and other institutions, and latterly a series of agreements between crown and papacy effected a share-out of church wealth that left spiritual matters out of account. Since 1487, royal control over appointments to the higher ecclesiastical offices had grown stage by stage, and in the 1530s the pope had begun to impose on the Scottish Church heavy taxation, which enriched the crown but dislocated ecclesiastical finance and embittered relations between the prelates and the people. Nobles and lairds might be attracted to the new religious doctrines that Scots scholars and traders encountered on the Continent; nobles and lairds might also be influenced by material considerations. By the 1530s they were gaining possession of much of the church's wealth on a hereditary or quasi-hereditary basis: clerics feued church lands to laymen, and laymen became collectors of church revenues and commendators of abbeys. The enriched laymen were prepared to support a Reformation that did not threaten their possessions, and perhaps some even felt compelled to take part in it to ensure that it did not so threaten. In addition, lairds relished the enhanced influence they would exercise in a church with greater lay participation.

Whether or not clerical shortcomings in the early 16th century

were worse than before, awareness of them was more general, and criticism, sometimes stemming from a genuine spiritual reawakening, was more openly stated. Sir David Lyndsay, the last great Scots poet for two centuries, used his play *Ane Satyre of the Thrie Estaits* to castigate the church without saying whether reform from within was possible. Reformers from within, countenanced by Archbishop John Hamilton, who gave his name to a Scots Catechism (1552), made little headway against vested interests.

3. Mary and the Scottish Reformation.—Mary's minority allowed the tension between ecclesiastical conservatives and francophiles on one hand, and Reformers and friends of England on the other, to increase. By the Treaties of Greenwich (1543) it was agreed that Mary should marry Edward, Henry VIII's heir, but the French cause was upheld by David Cardinal Beaton and Mary of Lorraine, the queen mother, and two English invasions (1544 and 1545) hardened Scottish resistance. The murder of Beaton (1546) did not reverse the trend, for his murderers received no effective English help and ultimately had to surrender St. Andrews Castle (July 1547) to a French expedition. A third English invasion and the defeat of the Scots at Pinkie (September 1547) left English forces in occupation of southeastern Scotland: French help against them was given only on condition that Queen Mary should be removed to France. The English were ousted, but the French hold on Scotland gradually tightened until, with Mary's marriage in 1558 to the dauphin Francis (afterward Francis II), it seemed likely that Scotland would be absorbed into the French monarchy.

National resentment against the French thus combined with the work of reforming preachers to stimulate preparations for revolt. In December 1557 some leading supporters of the new faith pledged themselves, in a "Common Band," to cooperate in politics and religion. In 1559, after Mary of Lorraine determined on stern action against Reformers, they took up arms. But, despite the preaching of John Knox (*q.v.*) and the plundering of monasteries by town mobs, the decisive campaign of 1560 was fought mainly between the government's French troops and the forces sent by Elizabeth I of England to prevent French hegemony in Scotland. Mary of Lorraine died in June 1560, and by the Treaty of Edinburgh, in July, both France and England undertook to withdraw their troops.

These events were decisive politically, but less than decisive for the Reformation. A Parliament in August 1560 abolished papal authority and adopted a reformed Confession of Faith; the organization of local congregations, which had started some years before, continued, and the Reformed Church found a central legislative body in the general assembly. But the legislation of August 1560 was not ratified by the queen, and the Reformed Church could not count on establishment should she return to Scotland. Nor could it have full endowment, as so much of the ecclesiastical wealth was already in lay hands. Knox and his fellow ministers produced in the *First Book of Discipline* (1560) a noble social program, providing not only for reasonable ministerial stipends but also for education at all levels and for poor relief. But it did not receive parliamentary approval and instead of receiving the bulk of the church's revenues, as they demanded, the reformers had to be content with an arrangement (1562) whereby they shared one-third of them with the crown.

Mary's husband died late in 1560 and she returned to Scotland in 1561. She was the Catholic queen of a Protestant Scotland and also the nearest heir to the English throne, by descent from Henry VII's daughter Margaret; her return thus made difficulties for both countries. Mary's brain and political sense were probably as keen as those of most of her contemporaries; but, in striking contrast to Queen Elizabeth, she sometimes put passion before policy, and this finally destroyed her when her somewhat lax Catholicism and the strength of noble faction alone would not have done so. For her bitter disputes with Knox *see* KNOX, JOHN. For the story of her marriage (1565) with the degenerate Henry, Lord Darnley, the birth (1566) of their son James, Darnley's murder, and Mary's marriage with the adventurer James Hepburn, 4th earl of Bothwell (the main suspect), and her imprisonment, forced abdication, escape (1568), and flight to England *see* MARY (*Mary Stuart*).

H. WAR AND PEACE, 1567–1625

Amid civil war between "Queen's Men" and "King's Men"—Mary's faction and the supporters of her son the young King

James VI (1567–1625)—two out of three short regencies ended in violent death. Elizabeth had detained Mary in England, for a Protestant regency in Scotland suited her better than a Catholic queen. She therefore ultimately aided James Douglas, earl of Morton, who became regent in 1572, to achieve stability. Many nobles had favoured Mary in the struggle: that her side lost speaks much for the political cohesion that the lairds and merchants, who tended to support James, had learned in the Reformation era.

1. The Church.—After Mary's deposition the government gave full recognition to the church settlement. In 1567 provision was made for the succession of ministers of the new church to the benefices of the old as they fell vacant. In 1573 an act provided for the deprivation of anyone enjoying a benefice of the old church who had not yet recognized the new. The new church benefited by Morton's Concordat of Leith (1572), whereby the crown was to appoint bishops with the approval of the church. This measure prevented bishopric revenues from wholly following those of the monasteries into the hands of laymen.

But such a compromise was repugnant to the second generation of Reformers, the first Scots churchmen who could be truly called Presbyterian. Led by Andrew Melville, a brilliant academic who lacked the political ability to compromise, they framed the *Second Book of Discipline* (1578). They demanded the wealth of the old church for the support of the new, condemned episcopacy, and advocated rule of the church by a hierarchy of ecclesiastical courts (to include elders as well as ministers), kirk sessions, presbyteries, synods, and the general assembly. Government of church and of state should be separate, but the spiritual power could instruct the secular in the godly exercise of its duties. The implication of this was theocratic rule by a caste of learned divines. Belief in such a polity was the basis of clerical opposition, then and later, to the kings of Scots. Melville was too unsubtle in his confrontation with the monarchy, and his program held little appeal for wealthy laymen. For a time political circumstances led James, who already strongly opposed the presbyterian system, to make concessions to Presbytery culminating in the "Golden Act" of 1592, which sanctioned the Presbyterian hierarchy of church courts. This delayed but could not prevent James's eventual triumph. From 1600 the bishops he had appointed sat in Parliament, symbolic of his determination to give the law to the church as well as to the state. From 1606, with the detention in London and later banishment of Melville and others, the clerical opposition was greatly weakened. By 1610 the civil and ecclesiastical status of the bishops had been fully reestablished. Since the church courts remained in being also, the system was moderate enough for most men; and James and his advisers were sensitive enough to the opposition to the beginnings of proposed liturgical changes—the Five Articles of Perth (1618)—to go no further.

2. James VI's Achievement.—Catholic influence at court had been suspected after the execution of Morton (1581). But, in the atmosphere of the 1580s, when Protestantism everywhere seemed threatened by Spain and the other Catholic powers, a league was concluded with England (1585–86), and James, now personally responsible for policy, in the following year virtually acquiesced in the execution of his mother, who had become the focus of every plot against Elizabeth. James inherited his mother's claim to the English throne, and to inherit the throne itself he had to retain Elizabeth's friendship while yet avoiding, if possible, giving offense to Catholic Scots or Catholic powers abroad. In fairness to James it must be said that the same course of action was called for in order to preserve his Scottish throne. With unruly churchmen and factious nobles to contend with, he was fortunate in possessing infinite guile and resource. His theories of royal rule by divine right, which became rigid by the end of his life, were initially evolved as the reasonable response of a scholarly man to the beliefs of Scottish Presbyterians and continental Catholics alike that in certain circumstances tyrannicide was not a sin. In pursuing his policy of conciliation James was lenient to his Catholic nobles even when the discovery of letters and blank documents (the "Spanish Blanks" affair, 1592), showed several of them to be in treasonable conspiracy with Spain. While he flirted diplomatically with the papacy and the Catholic states, he also corresponded with Elizabeth's minister, Robert Cecil (later 1st earl of Salisbury), and was thereby enabled to succeed peacefully to the English throne (as James I) in 1603.

The era of the Scots Reformation had seen the beginnings of a fundamental reorientation of the realm and its people. Endemic Anglo-Scottish warfare had been in a sense an artificial condition, and as it ceased it was replaced by a positive unifying factor, the need to defend the Reformation. Queen Elizabeth's Act of Supremacy (1559) showed that England had again broken with Rome; the Scots did so in 1560. The greater nation drew the lesser, as Henry VII is supposed to have said it would. The process began before 1603 and continued apace. The achievement of peace and amity within Great Britain was, however, balanced by a weakening of Scotland's continental ties and a sometimes slavish following of English example. The Scots language declined—the most effective teacher of standard English being the Authorized Version of the Bible (1611)—and Scottish institutions became slightly less distinctive throughout the following centuries.

Historians have often criticized James's rule in England. But no amount of royal wisdom could have wholly averted the political and social upheavals of 17th-century England, and Elizabeth had left a legacy of trouble. James's regal qualities may be better gauged from the way in which Scotland, which he saw only once between 1603 and his death in 1625, continued to be administered as well as under any previous king, by the team of royal servants James had created. John Maitland of Thirlestane, chancellor from 1587 to 1595, was one of the first of this group. These men were lairds or burgesses, who were frequently ennobled, often by the erection of former monastery lands into a temporal lordship for them, but who remained more dependent on royal favour and therefore more submissive than members of the older noble families. Such men held offices of state, sat as judges, or served as bishops. Some bishops, like Andrew Knox who helped pacify the Western Isles, had secular as well as ecclesiastical roles. James's rule was paternalist, and he regarded it as his function to impose order on all his subjects. He looked to God for approval rather than to the ruled for consent; yet there is little doubt that that consent was widely given.

3. Government and Economic Developments.—The Scottish Parliament, which had long consisted of prelates, nobles, and representatives of the royal burghs, was strengthened after 1587 by the admission of shire commissioners representing the "barons" (lairds), who had flocked to the revolutionary Parliament of 1560 and had found their way into the general assembly. But the crown had much influence in Parliament's composition, and it could control the Committee of the Articles (*see* PARLIAMENT: *The Parliament of Scotland*) which was the sole channel through which measures could come before the full House. The Privy Council, in which royal officials were the most regular attenders, carried out royal orders sent from London. It had extensive legislative as well as administrative functions, and also considerable judicial powers, which overlapped with those of the Court of Session and the Court of Justiciary. The former court, for civil cases, had emerged from the council early in the 16th century and had, under the name of the College of Justice, been endowed with church funds through a papal concession in 1532; and justice courts for criminal cases existed in various forms until the organization of the High Court of Justiciary in 1671–72. Local justice and administration had long been largely in the hands of landowners, for regality courts, baron courts, and even sheriff courts were heritable jurisdictions. James VI, as part of his general policy of reducing the nobles' power, attempted without success to foster justices of the peace and undermine the heritable jurisdictions, but it was only by slow social changes throughout the 17th century that the old domination of the magnates over the lower classes was to some extent broken down.

Good government was one of the reasons for the increased prosperity of Scotland in the late 16th and early 17th centuries. Taking into acocunt the international inflation of the period, it still seems that the average merchant and landowner tended to become richer; and the merchant, who received cash while the landowner would be paid rentals in kind, had ready money for furnishing his

house with imported luxuries. A few innovations were made in farming (*e.g.*, the use of lime on fields close to a natural supply), and, after 1660, attempts were made to encourage some manufactures (*e.g.*, linen) and to begin others (*e.g.*, glass) by protectionist devices such as the grant of monopolies and the control of imports. But this does not indicate a dynamic economy; nor does the enumeration of the main exports—grain (in good years), hides, wool, linen, coal, and salt, sent to France and throughout the North Sea and Baltic regions—or the imports of grain (in bad years), wine and other luxury foods and manufactures, timber, iron ore, and naval stores. The Scots economy was in fact a subsistence one, essentially rural and producing above all for its own needs. Until the roads were improved in the 18th and 19th centuries it could be little else, and as such, given a good summer, it sufficed. It was national vitality, and probably pressure of increased population, rather than simple dearth, that sent Scots to England; to Ulster when it was deliberately "planted" with settlers by James VI from 1610 onward; and, in substantial numbers, as merchants and mercenaries, throughout northern Europe and beyond. The lines of future economic development were being laid in closer trading ties with the more developed economy of England: after 1603 there were still two countries in one island, with a customs barrier between them (though with a great decrease in border lawlessness through the work of James VI), but their peoples came to enjoy a common nationality and various mutual trading concessions. The educational system, which in the 18th century produced trained manpower for Scotland's industrialization, was created in the 17th in the faith that godliness would follow good learning. The Reformed Church, though lacking most of the endowments of the old, nevertheless was instrumental in creating a network of parish and burgh schools that covered most of Lowland Scotland. An act of the Privy Council of 1616, which decreed the founding of a school in each parish, and later enactments, ensured that the work went on throughout the 17th century's turmoils. Andrew Melville brought discipline and the highest standards of scholarship in divinity and oriental languages to the universities of Glasgow and St. Andrews. Aberdeen (Marischal College, 1593) and Edinburgh (the Town's College, charter of 1582) were new foundations.

I. The Age of Revolution, 1625–89

1. Charles I.—James VI's son, Charles I (1625–49), grew up in England, lacking any understanding of his Scottish subjects and their institutions. He soon fell foul of a nobility restless in a Scotland that lacked the natural focal point of a royal court. His Act of Revocation (1625), rendering void all dispositions of royal or church property made since 1540, had the laudable aim of providing for the needs of the church. Besides, it is clear that Charles intended no program of confiscation without compensation. But the nobility regarded the secretiveness of the royal administration as alarming, the increasing use made of bishops in government as an affront, and Charles himself as standing too much upon his dignity to listen to discontented subjects. The king also caused widespread anger by high taxation, by the special demands made on Edinburgh to build a Parliament House and to provide a cathedral for the bishopric founded there in 1633, and by a Spanish and a French war that were intended to further English diplomacy, but also disrupted Scottish trading ties. The aristocratic leaders of the opposition found ideal material on which to build clerical and popular support. Charles and his Scottish bishops were "Arminian" enough in theology and fond enough of ritual and splendour in church services to make plausible the (wholly incorrect) suggestion that they were ready for compromise with Rome. The new Book of Canons (1635–36) and Liturgy (1637) therefore offended by their content, as well as by being authorized by royal prerogative alone. The National Covenant (1638) astutely collected national support for the opposition's pledge to resist Charles's innovations. Condemnation of popery was written into it for the benefit of those who feared that Charles might be a crypto-Catholic; others, more sophisticated, welcomed its implicit condemnation of a royal arbitrariness with religion and private rights that was contrary to all Scottish precedent.

The Covenanters humbled Charles in two almost bloodless campaigns, the Bishops' Wars (1639–40), and left him with no alternative to asking for money from an English Parliament, in which his opponents were strongly represented. Charles had authorized a general assembly of the Scottish Church (1638) and a Scottish Parliament (1639); the Covenanters packed these meetings, scrapped all the king's innovations, and abolished episcopacy. There was, therefore, by 1641 a revolutionary situation in both kingdoms, and in August 1642 war broke out between Charles and his English opponents. Both sides sought Scots help, which was soon accorded to the English parliamentary opposition. By the Solemn League and Covenant (1643) the English promised, in return for military aid, to help preserve Presbyterian Church government in Scotland, and, so at least the Scots believed, to set it up in England. James Graham, 1st marquess of Montrose, and others who then left the Covenanting side argued that by this second Covenant, and by certain constitutional constraints they had placed upon the crown, the Scots had gone unwarrantably far beyond the aims of the first Covenant. But those of the Scots who were prepared to make common cause with the English opposition, even if the English did have a more deep-seated quarrel with their king than the Scots, had reasoned justification; for it was realistic to expect that Charles, as soon as it proved possible, would withdraw concessions made to men whom he regarded as his enemies. Personal antipathies also helped to split the ranks of the original Covenanters—notably the antipathy between Montrose, forthright and fearless but conceited, and Archibald Campbell, 1st marquess of Argyll, sincerely devoted to the cause but equally devoted to the advancement of his family. Montrose's military efforts for Charles in Scotland were crushed in 1645, and by 1646 Charles had lost the war in England, too. When Charles surrendered to the Scots Army in England, the Scots failed to reach agreement with him and handed him over to the English. The Scots contribution to the English war effort had been substantial, but not spectacular enough to leave a sense of obligation; and the English Army under Oliver Cromwell, now eclipsing Parliament in English politics, preferred Independency to Presbyterianism in the church and did not propose to honour the Solemn League and Covenant. A conservative element among the Covenanters in 1647 reached a compromise, or "Engagement," with Charles, by which they promised him help in return for the establishment of Presbyterianism in both kingdoms for three years, and went to war on his behalf: their ill-planned campaign was crushed at Preston in 1648. The clerics, who had bitterly opposed this compromise, were now able, under the leadership of a few nobles such as Argyll, to purge the Scots Parliament and Army of all tainted with collaboration with the king. The execution of Charles by the English in 1649 genuinely shocked most Scots, who were prepared to fight for his son, Charles II, once he had been constrained to accept the Covenants and once Montrose had been executed (1650). Cromwell's victory over the Scots at Dunbar (1650) gave more moderate Scots the ascendancy again, but this brought no better military result. Another, and decisive, defeat of a Scottish royalist army at Cromwell's hands came at Worcester in 1651.

2. Cromwell.—Cromwell imposed on Scotland a full and incorporating parliamentary union with England (1652). This could not enjoy the popularity of a union by consent, maintained as it was by an army of occupation, but Cromwell's administration of Scotland was efficient, and his judges, some of them Englishmen, achieved an admired impartiality. Public order was well maintained, even in the Highlands after the collapse of royalist resistance in 1654. Some nobles underwent forfeiture while others were impoverished by fines that followed campaigning expenses. The dependence of lesser men on greater, by characteristically Scottish family and feudal ties, was systematically weakened by the government. Scots commerce, disrupted by the wars, was in the worst possible condition to take advantage of economic union with England, and legislation tended to leave Scottish economic interests out of account. Cromwell did not overturn Presbyterianism, but ensured toleration for others, save Catholics and Episcopalians. Nevertheless the Scots' total failure to impose "godly" ways on England engendered serious national demoralization. The "Protest-

ers," those Presbyterians who had denounced the more moderate line of policy taken following Dunbar, remained irreconcilable with their fellows.

3. The Restoration Monarchy.—The restoration in 1660 of Charles II (1660–85) was welcomed by many moderate men of both his kingdoms. Charles had learned much from his father's fate and was prepared to forget many injuries, though his government executed some Scots, including the marquess of Argyll. The Scottish administration retained several means of raising money evolved in the previous 20 years, such as the land tax on annual valued rent, and the excise. The bishops who had enjoyed power under Charles I, and, more particularly, the ministers of the church who had exerted much influence thereafter, had sometimes been social upstarts in the eyes of the nobles: aristocratic rule was now firmly reestablished. Nobles therefore had little temptation to place themselves at the head of ecclesiastical opposition to the crown when it arose. Charles, on the whole wisely, kept his Scots servants on a slack rein, and John Maitland, earl (later duke) of Lauderdale, the chief of them from the mid-1660s, made able efforts to hold together the various political and ecclesiastical factions. But Lauderdale's distribution of government patronage, and his and his colleagues' greed, provided ample scope for criticism by a growing parliamentary opposition. The Scots Parliament provided, as never before, an arena for genuine debate.

The ecclesiastical opposition was socially and geographically restricted, but intractable. In 1662 Charles formally restored church government by bishops, but these were to act in association with synods and presbyteries, much as under James VI's compromise. Private conventicles were forbidden. Charles seems not to have been moved by rancour toward the Covenanters, who had bullied him in the early 1650s, but merely by a desire to achieve the system that satisfied most people. Many laymen accepted his system, and few nobles opposed it. Approximately 270 ministers, however—just over a quarter of the total—were deprived of their parishes for noncompliance. The Pentland Rising (1666) was easily put down and was countered by an experimental period of tolerance by the government. The Act of Supremacy (1669) reminded bishops as well as Presbyterians that episcopacy was regarded simply as a means to royal control of a church at peace, and about half the "outed" ministers accepted Indulgences (1669 and 1672) that permitted them to resume preaching legally. Persons who still persisted in attending conventicles were strong only in the southwest and to some extent in Fife, and among the small lairds and common people. These men adhered to the "Protester" position, regarding Scotland as still bound by the Covenants, and having no respect for majority opinion. In another trial of strength with the government they were defeated at Bothwell Bridge (1679). The remnant of Cameronians (*q.v.;* from Richard Cameron, who in 1680 at Sanquhar declared Charles II deposed) remained in being, meeting governmental violence with further violence, and in 1690 refused to join a Presbyterian but uncovenanted Church of Scotland (*see* below). Their brave and fanatical "thrawnness" endeared them to later generations of Scots.

Charles's brother James, duke of York, was commissioner to the Scottish Parliament of 1681, and in 1685 succeeded as James VII of Scots and James II of Great Britain and Ireland (1685–88). Most Scots showed, by taking a self-contradictory religious test oath (1681) and by the parliamentary grant to him of the excise in perpetuity (1685), that they were prepared to support him despite his Catholicism. But he showed his ineptitude by requesting Parliament to grant toleration to Catholics (1686); this caused a near-defeat in the Committee of the Articles and stirred up unprecedented opposition to royal wishes in Parliament itself. James proceeded to a limited grant of toleration (February 1687) by use of the prerogative alone; but, though he went on to make the toleration a general one (June 1687), he merely aroused resentment among his Episcopalian supporters without gaining any compensating Presbyterian gratitude. Nevertheless, although many exiled Scots were at the court of William of Orange in Holland, the collapse (1688–89) of James's regime in Scotland was entirely a result of the Revolution of 1688 (*see* ENGLISH HISTORY) in England and the landing there of William.

4. Culture.—There had been a notable scholarly outpouring under Mary and James VI: George Buchanan (d. 1582) was the greatest European latinist of his day. Thereafter, Scots cultural streams ran deep but narrow. Religion and politics received disproportionate attention, and the cleverest men tended to be forced into public action or public writing. In this context Sir Thomas Urquhart of Cromarty (d. 1660), an eccentric polymath who achieved a near-perfect translation of Rabelais, is best seen as a late survivor of the Jacobean era. Samuel Rutherford (d. 1661), a Presbyterian controversialist, appeared at his best in private letters of spiritual guidance to his friends. James Dalrymple, 1st viscount of Stair, while eminent as a statesman, was above all one of the world's greatest legal theorists, giving Scots law its philosophical foundations in his *The Institutions of the Law of Scotland* (1681). Before 1707, the "Scottish Enlightenment" was dawning. In architecture the first signs were early: the reconstruction of the Palace of Holyroodhouse in Edinburgh during Charles II's reign, and the erection of Hopetoun House in West Lothian, begun in 1698. The Advocates' Library was founded in 1682 in Edinburgh, and a physic (*i.e.,* botanical) garden had been opened there in 1670.

J. THE ERA OF UNION

1. The Revolution Settlement.—James VII (d. 1701) having fled to France, William, now William III in England and Ireland, summoned (March 1689) a Convention of Estates (really the same assembly as Parliament, but meeting less formally). It listed James's misdeeds in the Claim of Right, and gave the crown jointly to William (II of Scots; 1689–1702) and his wife Mary II (1689–94), James's daughter. A series of crises throughout William's reign exposed his total lack of interest in Scotland and placed a strain on the system which had grown up whereby the Scottish ministry took orders not only from the monarch but also from the English ministry. But William's first major decision was probably right: episcopacy was abolished in 1689, and Presbyterianism reestablished the following year. As in 1662, the decision was taken on political grounds. More than half the clergy were forcibly ejected by their parishioners, or were formally deprived;

but against this must be set purges in the opposite direction while James had been commissioner and king. Jacobite resistance, confined to the Highlands, was insignificant after the defeat of its adherents at the Battle of Dunkeld (August 1689). Nevertheless, the government used tardiness to take the oath of allegiance as the pretext for having more than 30 of the MacDonalds of Glencoe treacherously murdered in 1692. The indignation this caused was unprecedented for such an event, but much of it was synthetic, whipped up by a parliamentary opposition who were loyal to William but factious and anxious for office, and whose campaign reached its climax in 1695. The patronage available to the government helped to ensure that it was never defeated, but debates in the Scots Parliament, which had been liberated by the abolition of the Committee of the Articles in 1690, became increasingly stormy. Further serious trouble resulted from Scottish attempts to end the country's economic stagnation (*see* below) by establishing (1698) a colony at Darién on the isthmus of Panama. With Spain and the climate both unfriendly, the colony was a costly failure (1700)—it is estimated that more than £200,000 and 2,000 lives were lost—and would have been so even without English hostility and refusal to give any help. But the colony had incurred this hostility by running counter to England's need to conciliate Spain in order to check France, and Scots resented the subordination of their interests to those of William's other kingdom.

2. The Union and its Results.—William had fought one war against France (1689–97), and on his death in 1702 bequeathed another (1701–13) to his successor, his wife's sister Anne (1702–14). These circumstances, following Darién, made a Union of Scotland and England seem strategically as well as economically desirable, but negotiations in 1702 found neither side sufficiently eager for agreement. That Union was achieved in 1707 is at first sight surprising, since intervening sessions of the Scots Parliament had been in a mood to break the English connection altogether. But by 1707 England's appreciation of its own strategic interests, and of the nuisance value of the Scots Parliament, was lively enough for it to offer statesmanlike concessions to Scotland and material inducements to Scots parliamentarians to accept Union. It is the astute self-interest of the Scots politicians, led by James Douglas, 2nd duke of Queensberry, and James Ogilvy, 1st earl of Seafield, more than their economic farsightedness, that impresses historians now. After all, the constitutional farsightedness of Andrew Fletcher of Saltoun, who as a Scots anti-Unionist was on the losing side, has often been dismissed as chimerical, though ideas like his, for an informal link between the two countries, underlie the modern Commonwealth.

The Union was an incorporating one: the Scots Parliament was ended and the Westminster one increased by 45 commoners and 16 peers representing Scotland. Scotland benefited by gaining free trade with England and its colonies, by the grant of a money "Equivalent" of the share of the English national debt that Scotland would assume, and by the explicit safeguarding of its national church and legal system. The Union survived the pinpricks of an English Tory government (1710–14) not wholly sympathetic to Scotland, and sometimes prompted by mischievous Scots Jacobite members of Parliament: the imposition (1711) of a duty on linen exports; the granting of toleration to Scots Episcopalians (1712); the restoration in the Church of Scotland of individual lay patronage (1712), that had been abolished in 1690; and the refusal of the House of Lords to let the duke of Hamilton sit by virtue of his British title of duke of Brandon. After this, and after Queen Anne's death in 1714, when the Jacobites missed their best opportunity, the worst crises of the Union were past.

Eighteenth-century Scotsmen were preoccupied with the fact of Union, and often spoke of "North Britain" rather than "Scotland." Englishmen were less self-conscious, but resented the number of ambitious Scots in England. An unusual display of Scottish feeling took place after the Porteous Riot of 1736 in Edinburgh (*see* Porteous, John), when in the House of Commons all but one of the Scottish members, who were usually subservient to the government of the day, voted against the ministry's attempt to punish Edinburgh for the riot.

Politically and administratively, the Union brought Scotland absolutely into dependence on decisions taken in London. Some Scots politicians learned this lesson well, and gained a measure of real power by making themselves intermediaries between the government and Scots who sought patronage from it: Archibald Campbell, earl of Islay (later 3rd duke of Argyll) and Henry Dundas, 1st Viscount Melville, were the most notable of these Scottish "managers." Dundas' position, with East India Company patronage at his disposal and William Pitt the Younger as his personal friend, was especially strong. On the other hand, some Scots politicians made themselves disagreeable by trying to use their ministerial influence in Scotland to gain more power within the ministry. To avoid giving any single Scots politician an entrenched position, therefore, the formal channel for transacting Scottish business, the third secretaryship, was allowed to lapse in the mid-18th century, and for over a century routine government business in Scotland was normally the concern of the lord advocate, the chief law officer. Duncan Forbes of Culloden, a law officer and judge, was outstanding among administrators for his fostering of trade and industry. One of his last official concerns was the ending of heritable jurisdictions in 1747, after the failure of the rebellion of 1745 (*see* below), with compensation paid to loyal subjects who had enjoyed jurisdictions. This was probably in intention mainly a piece of patronage, since the Highland chiefs had not had to depend on jurisdictions for their power, and in the Lowlands the more important jurisdictions had fallen into desuetude.

3. The Economy.—The Scots economy had made few spectacular advances in the 17th century, in spite of encouraging legislation, exemplified in the Parliament of 1681. The linen, coal, and cattle export trades gradually increased, and an ever greater proportion of these and other exports went to England. By the 1690s many of Scotland's traditional continental trading links were declining. England's wars caused disruption; and mercantilist-minded states increased their competition and raised their tariff barriers. In good years the Scots economy was still self-sufficient. The famine of the "ill years" (1695–99) of bad weather and bad harvests gave part of the psychological impetus for Darién: in the end, Darién prompted Scots in spite of themselves toward Union. In the absence of Union, Scottish industrialization could scarcely have taken place without investment by some continental power, say France—a situation England could hardly have tolerated.

The Scottish economy in the early 18th century remained backward in many ways. English customs and excise, and land tax yields before the Union were about 38 times greater than Scotland's, while the population ratio was only five to one. The discrepancy cannot be ascribed wholly to the more primitive nature of the Scottish governmental and revenue-collecting machinery. The economic benefits prophesied by some advocates of Union did appear, but only slowly. There was no immediate influx of capital on a scale large enough to boost the stagnant Scottish economy. Gradually, however, farming was revolutionized by enclosures that ended the old "run rig" (strip) pattern of fields, by crop rotations, and by long leases granted to "improving" tenant farmers. Gradually too the cattle and linen trades, and the entrepôt trade in American tobacco that was brought to Glasgow and thence taken to the Continent, made some Scotsmen prosperous. New banks were founded, and they joined the Bank of Scotland (founded 1695) in making available the capital necessary for expansion. In 1759 the quickening pace of development was symbolized by the founding of the Carron Iron Company, near Falkirk.

K. Aspects of Change

1. Jacobitism: the Highlands.—The Jacobites were seldom more than a nuisance in Britain. An expedition from France in 1708 and a West Highland rising with aid from Spain in 1719 were abortive; bad leadership in the rebellion in 1715 (known as "the Fifteen") of James VII's son, James, the Old Pretender (*q.v.*), and divided counsels in that of 1745 ("the Forty-Five") led by the Old Pretender's son Charles Edward, the Young Pretender (*q.v.*), crippled invasions originating in France that had in any case less than an even chance of success. The government was not always sufficiently prepared against invasions, but the generalship of John Campbell, 2nd duke of Argyll, at Sheriffmuir in 1715 sufficed to

check, and that of William Augustus, duke of Cumberland, at Culloden in 1746 to give the coup de grace to a Jacobite army. The Jacobites never had full French naval and military assistance, and support in Scotland itself was limited: not many more Lowland Scots than Englishmen loved the Stuarts enough to die for them. Many politicians, especially before 1714, corresponded with the royal exiles simply as a matter of insurance against their return, and in the dying days of Stuart hopes there were fewer people than there have been since who were struck by the romantic aura surrounding Prince Charles Edward, though the Highlanders' devotion in sheltering him after the Forty-Five still overcomes the historian's cynicism. A few extreme Presbyterians were prepared to trust a Catholic king rather than an uncovenanted Protestant one. Many northeastern lairds, often Episcopalian and sometimes perhaps subconsciously uneasy at the way in which the increasing commercial prosperity of the Forth-Clyde region was overshadowing their still primarily agricultural region, were ready to turn out. But in the main the Stuarts had to rely on the clans of the Gaelic-speaking regions, and Highland support in itself alienated Lowlanders. Not all Highlanders were "out" in the Fifteen or the Forty-Five: such clans as the Campbells and Munros, Macleods, and Macdonalds of Sleat were Hanoverian because Presbyterian, or through their chiefs' personal inclinations. Many clans were, however, Catholic or Episcopalian, and favoured a Catholic monarch: they were legitimists and reasonably so, since both James VII and his son James the Old Pretender appreciated Highland problems. These were the problems of an infertile land, overpopulated with fighting men who owed personal allegiance to their chiefs and were partly dependent on plunder to maintain their standard of living. It is hard to see what in the end could have happened to this society, other than what did happen: a series of attempts by the chiefs to emulate the new capitalist agriculture of the Lowlands, thus creating an impersonal cash relationship with their tenants and leaving those who were redundant in the new economy no alternative to moving south or overseas. But the catastrophe of the Fifteen and Forty-Five made this process more rapid and more painful. This is the central fact of the situation, even though the atrocities of government soldiers and the repressiveness of government legislation did very much less than economic and social forces to usher in the new order.

Many lairds in the West Highlands and Isles, who staved off depopulation of their lands in the late 18th century by encouraging the kelp industry, were ruined when it collapsed in the decade 1815–25. Other landowners introduced sheep, sometimes forcibly removing their tenants, in the "Highland Clearances," as agents of the Sutherland family did in Strathnaver, Sutherland, about 1810–20. By the 1880s Highland tenants or "crofters" faced a new problem. Deer forests had replaced sheep runs as the most immediately profitable land use open to landowners, and high rents were asked for the land that was still worked as crofts, even though common grazing land was at the same time, in many cases, taken away. Parliamentary agitation by the crofters, who voted for the first time in 1885, and by their Lowland sympathizers, and also sporadic outbursts of violence beginning in 1882 (the "Crofters' War"), secured an act of 1886 which gave the crofters security of tenure and empowered a Crofters' Commission to fix fair rents. Unlike their Irish counterparts, the Highlanders sought not ownership of their land but the imposition of certain standards of conduct and responsibility upon their landlords. The Highland problem remained intractable: the number of Gaelic speakers steadily declined. In the mid-20th century, however, forestry, tourism, and some industrial enterprise began to diversify the economy (*see* below, section VIII, *Economy*).

2. The Scottish Enlightenment.—No straightforward connection can be drawn between the Union and the exceptional 18th-century flowering of intellectual life known as the "Scottish Enlightenment." However, absence of civil strife permitted the best minds to turn, if they chose, from politics and its 17th-century twin, religion; and few of the best minds from 1707 onward were in fact directly concerned with politics. Philosophy, in which 18th-century Scotland excelled, was a proper concern for a country where for generations minds had been sharpened by theological debate. Scottish culture remained distinctive, and distinctively European in orientation. The historian and philosopher David Hume sought to remove Scotticisms from his speech, and the architect Robert Adam gained extra experience as well as income from being able to design buildings in London as well as in Edinburgh. Nevertheless, Adam drew most of his stylistic inspiration from the classical architecture he had studied in Italy, and Hume, "le bon David," was an honoured member of continental polite and intellectual society. Hume's *History of England* (1754–62) made his literary reputation in his lifetime; but it is his philosophical works, such as his *Treatise of Human Nature* (1739–40), that have caused the continuous growth of his reputation since his death, till he is seen as one of the greatest of all Scots. Adam Smith, author of *The Wealth of Nations* (1776), was the philosopher of political economy as Stair had been the philosopher of law. Henry Home, Lord Kames, may be singled out from many other significant figures to illustrate the versatility characteristic of the times. He was a judge, interested in legal theory and history; an agricultural reformer in theory and practice; a Commissioner of the Forfeited Estates (of the rebels of 1745); and a member of the Board of Trustees for Manufactures (which encouraged Scottish industries, notably linen). In poetry, there was a reaction, possibly against Union, and certainly against assimilation with England: revived interest in Scots vernacular poetry of the past was the herald of a spate of new vernacular poetry, culminating in the satires of Robert Fergusson and the lyrics of Robert Burns. Some of the greatest Gaelic poets, such as Alexander MacDonald, were writing at this time too.

The Scots educational system, its foundations so securely laid throughout the previous century, made possible, though neither it

nor any other single factor could be held to explain, this extraordinary cultural outpouring. The Scottish universities enjoyed their heyday, with Edinburgh notable for medicine and preeminent in most other subjects. Gradually the regents who taught students throughout their university course were replaced by professors specializing in single subjects. That students seldom troubled to graduate was little disadvantage in an age when appointments depended on patronage; and, not being bound by a rigid curriculum, they were able to indulge the Scot's traditionally wide intellectual curiosity by attending lectures in a variety of subjects. Scientific study was encouraged, and practical application of discoveries given due place. Francis Home, professor of *Materia Medica* at Edinburgh, studied bleaching processes and plant nutrition; and James Watt, instrument-maker to Glasgow University for a time, was there encouraged to work on the steam engine, to which he was to make crucial improvements.

3. Moderatism.—Moderatism was the name given to the climate of opinion prevailing in the 18th-century Church of Scotland. Partly in reaction to the amount of blood spilled in previous times over ostensibly religious issues, many ministers paid more attention to intellectual accomplishments or social graces than to the fruits of the spirit. At its best, this tendency produced William Robertson, historian, clergyman, and principal of Edinburgh University, a man of rare learning and tolerance. At its worst it bred callousness to the people's spiritual and material needs, and ultimately produced another reaction of opinion. This reaction was delayed because many of those who still wished to debate theology, to maintain severe moral standards, or to appoint ministers without reference to lay patrons made perhaps a tactical mistake in adhering to one or other of two secessions (of 1733 and 1761) from the Church of Scotland, thus leaving the field clear for their opponents. The older and more rigid of the Secession Churches ultimately itself split into four.

4. The American Revolution.—The American Revolution (1775–81) had important repercussions for Scots. Many Scots emigrants, especially Highlanders, were involved; some fought for Britain against the colonists. The tobacco merchants, who had played the greatest single role in the development of Glasgow and the west of Scotland, were prompt in 1776 in transferring their money to other trade routes, notably that bringing sugar from the West Indies, and to industries, notably cotton manufacture. This industry benefited from the expertise gained in linen manufacture, and, remaining especially important in the west, was Scotland's leading industry from about 1800 to 1830. Events in North America, and then the Revolution in France (from 1789) led Scotsmen to question the oligarchic basis of the British constitution. Self-perpetuating and corrupt town councils returned 15 of the 45 Scots members of Parliament; the franchise for the counties, where the other 30 commoners were elected, was based on ownership of land, and was in theory broad enough to give the lairds a say. But the feudal basis of Scots conveyancing gave antiquarian lawyers ample scope to manufacture votes in the interest of a few nobles, who thus determined the elections.

5. Politics.—Agitation for constitutional change was considered treasonable by many conservatives during the years (1793–1815) when Britain was fighting revolutionary France. Several advocates of universal suffrage, including a young Glasgow lawyer, Thomas Muir of Huntershill, were sentenced to transportation by Robert MacQueen, Lord Braxfield, in 1793. After repression had broken this first radical wave, postwar industrial depression produced another: the "Radical War" of 1820, an abortive rising of some workers in the Glasgow area. Intellectual campaigning of a more moderate sort had greater short-term success, and the *Edinburgh Review*, founded in 1802 by a group of young lawyers led by Francis Jeffrey and Henry Brougham, was influential in radical politics and in literature. Edinburgh life was particularly brilliant during the years of the war with France, when Englishmen as well as Scots, unable to study abroad, found Edinburgh University more attractive than ever. Outstanding in this period was Sir Walter Scott, although not till 1827 was he known to be the author of the Waverley novels. Scott's greatness as a novelist lay in the way he took Scottish society as a whole for his main character, and his best books are a lament for an era he knew was dying, the organic society of preindustrial Scotland.

6. The Disruption.—The French Revolution, seen as the ultimate product of the intellectualism and skepticism of the 18th century, stimulated an Evangelical reaction against Moderatism within the Church of Scotland. The Evangelicals also felt Moderatism had no answer to the material and spiritual squalor of the industrial towns. Many Evangelicals (including over a third of the ministers) broke with the Church of Scotland in the Disruption of 1843: they were determined to do without the benefits of Establishment so long as the state upheld patronage and other institutions that were believed to hinder a radical reshaping of the Church. Those breaking away, led by Thomas Chalmers, formed the Free Church of Scotland. More than the 18th-century secessions, this much bigger defection stung the Church of Scotland into reexamining its own conscience. Less beneficially, it produced a wasteful competition in building churches and made impossible Chalmers' dream of a voluntary system of poor relief run by the Church. The Scots opponents of voluntary poor relief were thus greatly strengthened; and, led by W. P. Alison, an Edinburgh medical professor whose work during epidemics had determined him to help the poor obtain better food as a means of disease prevention, this faction brought in an act (1845) making it almost compulsory for a parish to levy an assessment for poor relief. In strict statutory theory, however, the able-bodied unemployed remained outside the scope of this relief till the Poor Law Emergency Provisions (Scotland) Act of 1921.

The Catholic and Episcopalian Churches had never really gained the deepest spiritual allegiance of the Highlanders: this was shown in the later 18th century, when a conservative and morally strict brand of Presbyterianism became rooted in the northwest. Many Highlanders left the Church of Scotland in 1843 for the Free Church, where they felt they perceived more Evangelical fire. The most important development among the smaller (and mainly Lowland) Presbyterian sects was the emergence (*c.* 1800) of Voluntaryism, a belief—new in Scotland—in denying oneself as well as one's opponents the benefits or disadvantages of Establishment.

L. 19th-Century Scotland

1. The Industrial Revolution.—The Scottish Industrial Revolution was in full swing from the 1820s. Linked with this, partly as cause and partly as effect, in a way historians have not altogether disentangled, was a dramatic upsurge of population. There were perhaps about 1,000,000 people in Scotland in 1700. By 1800 there were more than 1,500,000 and by 1900 nearly 4,500,000. The manufacturing towns showed spectacular increases. Hundreds of thousands of Irish emigrants went to Scotland in the 19th century, notably during the Irish potato famine of 1846–50. In some country regions there was a population decrease as people moved to the towns, to England, or overseas. Part of the overall increase was the result of improved medical care that had lessened the ravages of epidemic diseases by the mid-19th century. Much of the food for the increased population was supplied by progressive Scottish agriculture: farming in the southeast was celebrated throughout Britain for its efficiency in the early 19th century, and the northeast became famous for its beef cattle, Ayrshire for its milking herds.

But the key advance was in heavy industry, which from about 1830 took the industrial primacy from textiles, at a time when industry as a whole had replaced agriculture as the nation's chief concern. Coal production rose, as did that of iron, with James Beaumont Neilson's hot-blast process (1828) making Scottish ores cheaper to work. Major canals, like the Forth and Clyde, completed in 1790, enjoyed a short boom before being rendered obsolescent by the railways, of which the Glasgow to Garnkirk (1831) was noteworthy for using steam locomotives (rather than horses) from the start. Above all, Scottish international trade was catered to, and Clydeside's reputation made, by the building of ships. Robert Napier was the greatest of many great Scots marine engineers.

As far as measurable factors like real wages and dietary standards are concerned, there is little agreement among historians

on the immediate effects of industrialization on the lives of Britain's workers. But there were undoubtedly deep psychological disturbances inherent in the move to squalid industrial towns and the submitting to monotonous and inexorable factory disciplines; and the Scottish Industrial Revolution, which occurred later and more swiftly than that of England, produced by the 1840s a class-conscious and militant proletariat. The workers' grievances were real enough. The controversy over voluntary or state poor relief, not resolved till 1845 (*see* above), delayed developments in other directions. Only in 1867 was a comprehensive Public Health Act passed. The overcrowded and filthy slums, consisting often of buildings unsatisfactory from the start, nevertheless acquired an awful semipermanence through the easy availability of building stone. Such neighbourhoods as the Gorbals in Glasgow, and the part of Edinburgh described in G. Bell's *Blackfriars' Wynd Analysed* (1850), became notorious. Improvement was made, for the proportion of the population living in one-room houses fell from 27% in 1861 to 8.7% in 1911, though the proportion of people (about 40%) living in two-room houses remained constant. In the first half of the 19th century epidemics had been common and deadly, cholera claiming more than 10,000 victims in 1832. Improvement in this respect was to some extent balanced by the fact that it was as late as 1897 that infant (first-year) mortality reached its peak of 138 deaths per 1,000 live births.

Development of working-class cohesiveness was uneven in different places and occupations. Cotton spinners and weavers were forming unions about the time that coal miners were freed by acts of Parliament (1775 and 1799) from being tied to their places of work. Trade unions, whose previous illegality in England was confirmed by the Combination Acts of 1799–1800, achieved the same negative status in Scotland for the first time by a series of judicial decisions culminating in 1813—a mark of public recognition if nothing else. The ban was lifted in both countries in 1824, although various legal disabilities remained. Cooperative movements ranged from the practicality of retail stores to the idealism of the community at Orbiston near Motherwell (1826–27) that was inspired by the work of the reformer Robert Owen.

Scottish Chartism was a vigorous political movement of the workers in the decade from 1838, especially in Glasgow. It stressed moral rather than physical force, and sought to pursue the long-term aim of amelioration of living and working conditions by means of education and social reform.

2. Politics and the Church.—An installment of parliamentary (1832) and burgh (1833) reform ended fictitious county votes and corrupt burgh caucuses, but it disillusioned the working classes by failing to give them the vote. As in England, they had to await the 1867 and subsequent Reform Acts. But the great bulk of the Scots middle classes were delighted with the Whigs (whose lord advocate from 1830 till 1834 was Francis Jeffrey) who had brought the reforms. The Whig Party, or Liberal Party (as it became known in the 1860s), dominated Scottish mid-19th century politics; and William Ewart Gladstone, of Scots parentage, was the great Liberal hero, whose moral dynamism and fire far outweighed in Scottish eyes his High Church Episcopalianism.

Benjamin Disraeli and the Conservatives wooed Church of Scotland opinion, in the short run unsuccessfully, by abolishing patronage in 1874. Nor did this development deter the Free Church, which still officially approved the principle of Establishment, and the United Presbyterian Church, formed by some of the sects in 1847 on an explicitly voluntaryist basis, from campaigning in the 1880s for the disestablishment of the Church of Scotland. There were general elections in 1885 and 1886. In the first of these some voters showed they feared that the Church of Scotland was in danger and that the Liberals would not save it. The following year many more erstwhile Liberals had become convinced by Gladstone's conversion to Irish Home Rule that his party was acquiescing in the destruction of Protestantism. The result was that, of the 60 Liberals elected in 1886 (out of a total of 72 members provided for Scotland in the 1884–85 Reform Act) 17 adhered to the Conservatives because of their common desire to maintain the Union between Great Britain and Ireland. The group's successors ultimately joined the Convervatives, who in Scotland are still generally termed "Unionists." The Liberals retained their majority of Scottish seats, but further defections in the 1890s, by working-class militants to the left, and by working-class and other jingoists to the right, resulted in the unprecedented event of the party's retaining only a minority of Scottish seats in the 1900 general election. In Church affairs 1900 saw the creation of the United Free Church, by union of the Free and United Presbyterian Churches on an explicitly voluntaryist basis. Some Free Church members, especially in the Highlands, broke away.

3. Economy in the Late 19th Century.—The Scots economy enjoyed the full benefits of mid-Victorian prosperity. By the 1880s, however, more difficult times had come and yet had failed to provoke an adequate response. Imports of wheat from North America from the 1870s onward, and of refrigerated meat thereafter, hit Scottish farming; but because Scots soils and climate had made Scots farmers adaptable, and ley (lea) farming common, the agricultural slump was less severe than in many other parts of Britain. Other countries were overtaking Britain's industrial lead, and Scots inventiveness was less in evidence than a century before. The Scots economy was concentrated on a dangerously narrow range of heavy industries, with shipbuilding dominant. Steel was becoming important, and because Bessemer steel was not thought suitable for ships, Scots steelmakers abandoned it almost entirely in favour of the open-hearth process. This decision narrowed the scope for steel-using industries in Scotland, and had repercussions as late as 1932 when it was the main factor behind the move of the firm of Stewarts and Lloyds to England. Because the ironmasters' demand for coal declined, a dangerously high proportion of coal production had to be exported.

4. Move to the Left.—Trade unions of skilled workers had had an uninterrupted existence since the mid-19th century. By the 1880s groups of unskilled workers were being organized. Various factors delayed the permanent organization of the miners till this period too, when there emerged from their ranks a major leader, James Keir Hardie. Failing to engage the Liberals sufficiently in support of organized labour, he helped form the Scottish Labour Party in 1888. In 1893 he created the Independent Labour Party (I.L.P.) for Britain as a whole, and this body in 1900 federated with the trade unions for the purpose of running the Labour Party (given its present name in 1906). Scottish political opinion moved left in the years before 1914, with Liberal fortunes reviving—partly because of the able leadership (1899–1908) of Sir Henry Campbell-Bannerman, a Scot—and three Labour M.P.s being elected.

M. Modern Scotland

1. World War I and After.—The war of 1914–18 had a great impact on Scots society, with 74,000 lives lost, and industry mobilized as never before in a coordinated national effort. From 1915 the Clyde Workers' Committee stubbornly opposed government action to modify established standards of pay and conditions for the duration of the war. The committee was the most active group of its kind in Britain, and this industrial militancy survived into the 1920s: the Scots trade union leaders did not, in the General Strike of 1926, lag behind their rank and file in resoluteness as did their English counterparts. The collapse of the wartime boom in 1920 began a period of economic depression in Britain, in which Scotland was one of the worst-affected regions. The war had disrupted the export pattern for staple Scottish products such as coal, and left behind it surplus world productive capacity for such traditional Scottish manufactures as steel and ships. At one point late in 1933 more than 30% of the insured workers in Scotland were unemployed. The seriousness of this is brought home when it is remembered that, already, in the decade 1921–31, nearly 400,000 people, out of a population of fewer than 5,000,000 had gone in search of work to England or overseas. Statistics are powerless to reveal the demoralization of the unemployed. The 1930s was a time of gradual improvement, with work on Clydeside's great ship, the "Queen Mary," being resumed in 1934 after more than two years' suspension.

Economic distress bred political radicalism. The Liberals were eclipsed, and in most seats the real contest was between the Union-

ists and Labour, which became Scotland's biggest single party for the first time in the election of 1922. Few Scots took their radicalism as far as did Willie Gallacher, in whose political education Lenin took a personal interest, and who was Scotland's only notable Communist M.P. The death (1930) of John Wheatley, who had been minister of health in the first Labour government (1924), deprived left-wingers in the Labour Party of a skilled leader, and counsels of moderation in the party prevented its taking any very distinctive initiative on the economic crisis. Ramsay MacDonald, a Scot who had led two minority Labour governments, agreed to form a national government in 1931. The Labour Party refused to participate, disowned MacDonald, and was heavily defeated at the polls, in Scotland as elsewhere. This Labour Party independence of mind was insufficient for the I.L.P., now largely Scottish and largely leftist in membership, and in 1932 it imitated the religious seceders of the previous two centuries by walking out of a body it had failed to dominate. Another political product of economic distress was the Scottish National Party, formed in 1934. It showed more literary than political vigour before World War II, but afterward was well run if small in scale.

2. World War II and After.—During World War II Scotland sustained some 34,000 deaths in action and 6,000 civilians were killed, many in air attacks on Clydeside. The outstanding Scot on the home front was probably Tom Johnston, a Labour M.P. who acted as secretary of state for Scotland in the wartime national government. He was active in setting up the North of Scotland Hydro-Electric Board in 1943. After 1945 better worldwide economic circumstances and a degree of government action in certain sectors (*e.g.*, agriculture) largely prevented a second postwar slump. The economy was diversified with the introduction of a substantial motor industry centred on Bathgate in West Lothian (1961) and Linwood in Renfrewshire (1963). An atomic reactor was built in Caithness and two atomic power stations in the Southwest: this helped to hasten the further decline of the coal industry. Scots industry remained vulnerable in a recession, and increasing English or overseas ownership of Scottish industrial concerns took decisions on any cutback more than ever out of Scottish hands. Slum-clearance programs and the building of new towns, and nearly full employment for most of the country for much of the period, began to bring proper minimum standards of life within the reach of almost all. Unionists in Scotland failed to match the Conservatives' dominance in England in the 1950s, and Labour strength in industrial centres was accompanied in the 1960s by signs of Liberal revival in the countryside.

3. Scottish Culture and Institutions.—Scottish culture was, for most of the 19th century, provincial in all the worst senses. There were some exceptional figures. Thomas Carlyle, historian and essayist, was a typical Scot of an older type in his philosophical bias and openness to continental influences. Robert Louis Stevenson was a novelist with a fine intuitive understanding of Scotland's past. Most other outstanding figures were in some ways isolated men, like Sir Patrick Geddes, a professor of botany who was better known as a pioneer of town planning, and Charles Rennie Mackintosh, the architect of the seminal Glasgow School of Art—men who were more acclaimed abroad than in Scotland. The 20th century brought a notable revival. While the dramatist James Bridie should be mentioned, poetry was the most fruitful field. Some writers sought a synthetic Scots language by drawing on words from all the regional dialects. Others revitalized a living language, Gaelic. Younger men, laying less stress on Scottishness, did good work in English. But the major figures were the Gaelic poet Somhairle Macghill-Eathain, and the polymath Hugh MacDiarmid. MacDiarmid (C. M. Grieve), a nationalist and Communist, was a poet of stature who wrote superior verse in a synthetic Scots based on various dialects and literary sources, in Lallans, and in English.

Scottish local government was progressively democratized. County councils were created in 1889, superseding for most purposes the commissions of supply that had functioned since Charles II's reign. As elsewhere, pressures existed for the creation of larger units, and gave rise to such legislation as the Local Government (Scotland) Act of 1929; but in the small burgh Scotland still retained an organ of truly local government that had spanned seven centuries. Demands for devolution of government within the United Kingdom led to the creation of a Scottish secretaryship (1885), which became a secretaryship of state in 1926 and transferred its offices from London to Edinburgh in the 1930s.

Scottish education retained characteristic virtues but lost its preeminence. After 1945 there was increasing subject-specialization in the upper forms of schools. Introduction of the "leaving certificate" examination (1888), normally necessary for university entrance, and subsequent regulations, and after 1945 the pressure of numbers, narrowed the doors of Scottish universities that were traditionally open to all who could stand to benefit by their teaching. In the universities, the Universities (Scotland) Act of 1889 provided a framework for higher scholarly standards at the undergraduate level at the expense of the traditional breadth of learning. These changes were the result of uncritical emulation of English models, as well as a response to the irresistible pressures of an ever more competitive world. One answer to educational challenges was the decision in the 1960s to create four new universities: at Edinburgh and at Glasgow by upgrading colleges of technology, at Dundee by giving autonomy to a university college, and at Stirling by a new foundation.

Scottish Church life remained distinctive. The Church of Scotland benefited in 1929 from union with all but a small part of the United Free Church. This was on a basis of partial disestablishment that still left the church protected by a royal oath taken at the coronation, and aided by a levy on land. The Catholic Church was the second largest, mainly because of the large-scale Irish immigration of the 19th century. These and many smaller denominations kept the proportion of active churchgoers in the population higher than in many Western European countries.

Scots law remained one of the nation's least popularly acclaimed yet most lively institutions. Appeal from the Court of Session to the House of Lords had existed since 1711 (though not specifically provided for in the Act of Union): through this door alien doctrines sometimes entered Scots law, though the danger was decreased by the creation in 1876 of Lords of Appeal, among whom there have always been Scots lawyers. Nor did legislation always take Scots law properly into account. Yet Scots law survived, and its position was recognized in 1965 by the creation of a separate Scottish Law Commission to examine legal reform. *See* also SCOTLAND, CHURCH OF; SCOTS LAW; SCOTTISH LITERATURE; and biographies of kings and notables mentioned. (J. M. SI.)

VI. POPULATION

At the census taken in 1961 the population of Scotland was 5,179,344 (females 2,696,610). This was an increase of 1.6% on the number enumerated at the previous census of 1951 and continued the series of intercensal increases recorded at every census except 1931, when a decrease of 0.8% on the 1921 figures was recorded. Since the mid-19th century the population has approximately doubled. At the 1841 census the total population enumerated was 2,620,184, which represented an increase of 1,000,000 on the total at the first official census in 1801. At the end of the 15th century it is estimated that the population did not exceed 500,000—Edinburgh having about 20,000 inhabitants, Perth about 9,000, and Aberdeen, Dundee, and St. Andrews about 4,000 each.

Since 1861 there has been a net emigration from Scotland to other countries of about 1,900,000, of whom about 1,400,000 have emigrated since 1900. In 1921–30 emigration was over 390,000, or about 8% of the population at the beginning of the decade. Because the age groups affected were in the lower range, the consequential loss was greater than the numerical total suggests. In the next decade and during World War II the outward flow of migration was checked, and in the years 1931–51 the net loss was about 220,000, mainly to England. After 1951 it averaged about 25,000 a year.

There has also been an appreciable inflow of population. At the 1931 census 346,050 of the population (7.14%) were born outside Scotland. In 1961 the number was 415,001, of whom 246,917 were born in England and Wales, 37,308 in Northern Ireland, and 39,670 in the Republic of Ireland.

If the population was evenly distributed throughout Scotland,

it would have amounted in 1961 to 170 per square mile. Actually, by far the largest part of the country had a population density of less than one person per square mile, the maximum degree of concentration being found in the highly industrial area lying approximately between the upper reaches of the Firth of Clyde and the Firth of Forth. A secondary but much smaller concentration is found along the southwestern and the eastern coasts. During the period 1931–61 there was a slight loss of population in most of the northern and border counties, and a more than compensating gain in the central industrial area. The population in the different counties is shown in the table.

Area and Population of Counties in Scotland
(1961 census)

Counties		Area (sq.mi.)	Population
Total		30,405	5,179,344
1. Northern:	Zetland (Shetland)	551	17,812
	Orkney	376	18,747
	Caithness	686	27,370
	Sutherland	2,028	13,507
2. Northwestern:	Ross and Cromarty	3,089	57,642
	Inverness	4,211	83,480
3. Northeastern:	Nairn	163	8,423
	Moray	476	49,170
	Banff	630	46,454
	Aberdeen*	1,971	321,783
	Kincardine	382	25,564
4. East Midland:	Angus*	874	278,399
	Perth	2,493	127,056
	Fife	504	320,692
	Kinross	82	6,702
	Clackmannan	55	41,394
5. West Midland:	Stirling	451	194,876
	Dunbarton	241	184,559
	Argyll	3,110	59,390
	Bute	218	15,170
6. Southwestern:	Renfrew	225	338,872
	Ayr	1,132	342,822
	Lanark*	898	1,626,424
7. Southeastern:	W. Lothian	120	92,768
	Midlothian*	366	580,329
	E. Lothian	267	52,677
	Berwick	457	22,437
	Peebles	347	14,156
	Selkirk	268	21,052
8. Southern:	Roxburgh	665	43,183
	Dumfries	1,075	88,440
	Kirkcudbright	897	28,870
	Wigtown	487	29,124

*Includes counties of cities.

Births (1951–60) were 950,142, averaging annually 95,014. There were 102,691 births (1963), a rate of 19.7 per 1,000. Births per 1,000 married women aged 16–44 (1963) were 145.2. The average family size of women 45–50 (1961) was 5.6; in 1911, 5.08. The average death rate (1951–60) was 12.1 per 1,000, a drop from 22.1 in 1861–70. The average marriage rate (1951–61) was 8.1 per 1,000; 6.9 in 1921–30. During and after World War II it rose to 9.4 (1945), being higher in the central industrial area than in the north or south. The Marriage (Scotland) Act, 1939, abolished irregular marriages by declaration, including "Gretna Green marriage" and "marriage before the sheriff," instituting a new form of civil marriage, to be contracted after publication of notice in the office and presence of registrars.

The populations of the largest towns (1961 census) were: Glasgow 1,055,017, Edinburgh 468,361, Aberdeen 185,390, Dundee 182,978, Paisley 95,750, Greenock 74,560, Motherwell and Wishaw 72,794, Coatbridge 53,825, Kirkcaldy 52,390.

During the period 1951–61 speakers of Gaelic declined by 14,469 to 80,978 of whom 1,974 spoke no English. The four principal Gaelic-speaking counties were Ross and Cromarty, Sutherland, Inverness, and Argyll. In 26 counties less than 1% of the population spoke Gaelic.

The Church of Scotland is the national church and the most influential and powerful religious body in Scotland. In 1961 members numbered 1,292,617. The Roman Catholic population in Scotland (including children) was estimated (1961) to be over 792,000, with marked concentrations in Glasgow and the neighbouring towns, where many Irish immigrants have settled. The Episcopal Church in Scotland had about 97,500 members in 1961. Other religious groups include the Baptists, Methodists, Congrega-

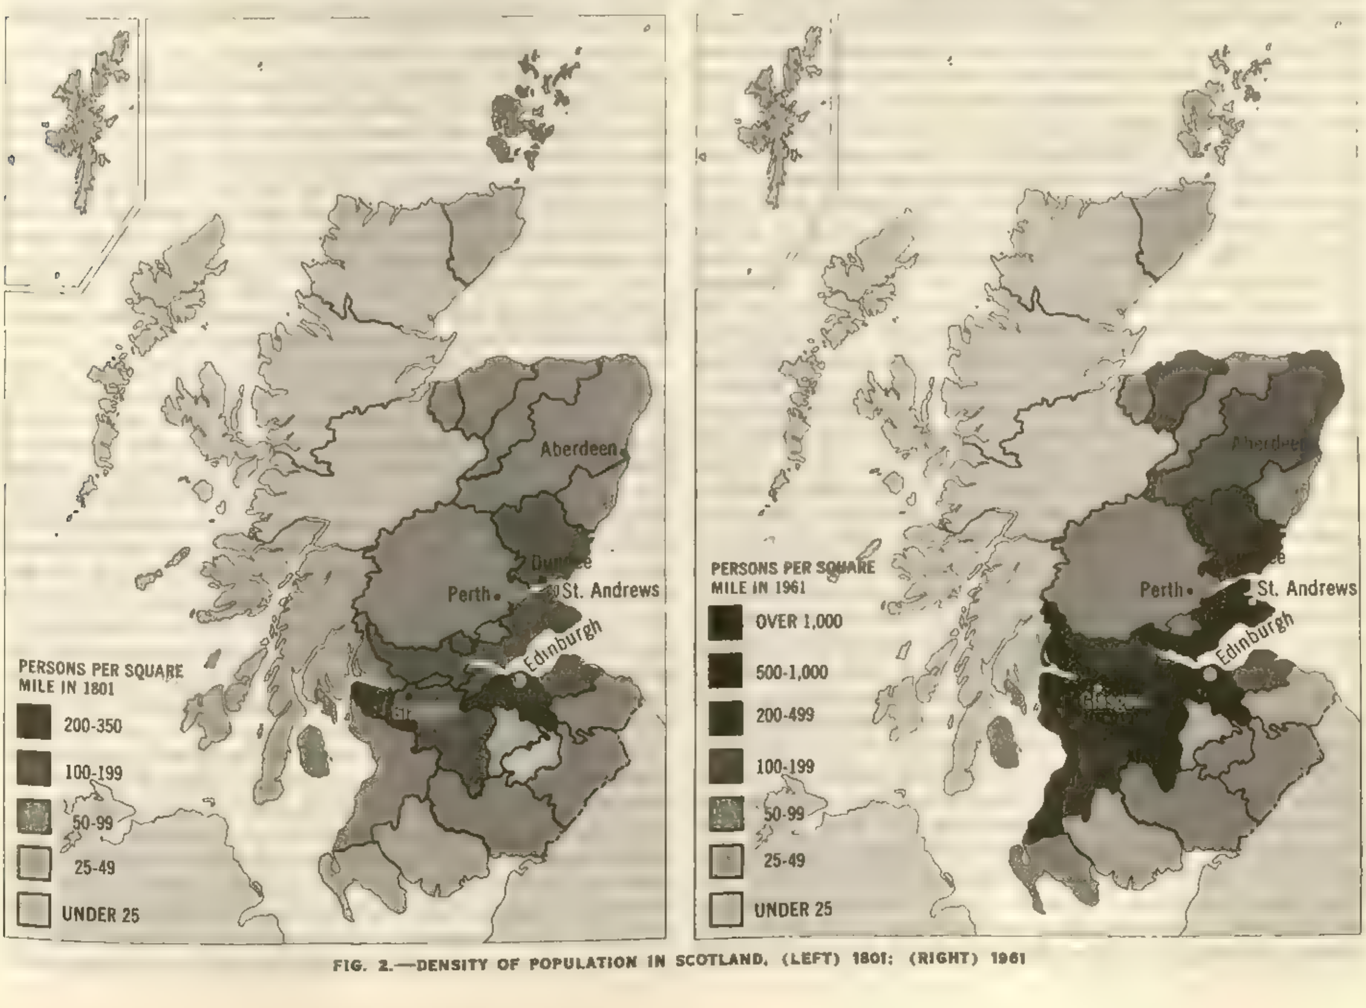

FIG. 2.—DENSITY OF POPULATION IN SCOTLAND, (LEFT) 1801; (RIGHT) 1961

tionalists, and Unitarians, while there is also a Jewish community of about 15,000, mainly concentrated in Glasgow. *See* also PRESBYTERIANISM; SCOTLAND, CHURCH OF; SCOTLAND, FREE CHURCH OF; UNITED FREE CHURCH OF SCOTLAND; SCOTLAND, EPISCOPAL CHURCH IN.

VII. ADMINISTRATION AND SOCIAL CONDITIONS

Central government administration is discussed under GREAT BRITAIN.

1. Local Government.—Scottish local government has its antecedents in the burghs, shires, and parishes of medieval Scotland. The burghs were primarily settlements of merchants and craftsmen, often with special privileges and property granted for the fostering of trade. The shire was the area over which the sheriff, as the royal representative, was responsible for law and order. The parish was centred on the church and concerned itself with the relief of the poor and with education. In the 19th century, the Industrial Revolution and the attendant huge increase in population in central Scotland brought pressing new problems of local government and at the same time a demand for more democratic control. Throughout that century there was a twofold movement: to set up town councils for new communities; and to reform the town councils of the old burghs. Elected county councils were constituted in 1889.

The present system was set up in 1929. The country is divided into 33 counties, two pairs of which—Perth and Kinross, and Moray and Nairn—are combined for certain purposes; there are also large and small burghs and four counties of cities (Edinburgh, Glasgow, Dundee, and Aberdeen); the part of the county outside the burghs is known as the landward area and is divided into districts. Local government is by town councils, county councils, and district councils. The powers of town councils vary according to the degree of importance of the burgh. In the counties of cities the town council is responsible for all the work of local government; in the 20 large burghs (broadly, burghs with more than 20,000 people) the town council performs all functions except education and valuation for rating and in a few is responsible for police; in the 176 small burghs the town council is responsible for such services as housing, water supply, and cleaning, but another large sector of local government work (including education, police, classified roads, and local health services) is the responsibility of the county council. In the landward area the county council is responsible for all the main work of local government; certain minor duties mostly concerned with amenity are entrusted to district councils. The latter may also exercise powers delegated to them by the county council.

Thus the county council as a body of representatives from the landward area of the county exercises certain local functions within that area; with the representatives of the small burghs added to it other functions are exercised within the landward area and also in the small burghs. When representatives of small and large burghs are added, the county council controls education in, and is the valuation authority for, the whole county.

Town council elections in burghs are held annually to replace the third of the council who have been longest in office. The whole of each county council is elected once in every three years. The district councils are elected along with the county council.

The cost of the services provided by the local authorities in Scotland is met by rates, government grants, and miscellaneous income, and, to meet expenditure of a capital nature, by the raising of loans. Rates are levied on the occupiers of lands and heritages on their ratable value, as shown in the valuation roll; properties are revalued every five years under the Valuation and Rating (Scotland) Act, 1956, but a new roll is made up each year to include new properties and to give effect to "material changes of circumstances" between revaluations. There are now three main kinds of government grants. Firstly, grants are still paid toward the cost of certain specific services (such as housing, roads, police, and civil defense) and are a given percentage of approved expenditure, except in the case of housing, the grant for which is largely on a unit basis. Secondly, many of the former grants for specific services, including those for education, and the health, fire, and child care services, have been replaced since 1959 by the general grant. The total general grant for Scotland is determined by reference to the latest available information of expenditure by local authorities on the relevant services, to likely fluctuations in the cost of providing them, and to the need for developing them in relation to the general state of the economy. The total grant is then distributed to the local authorities on a basis that does not relate to the actual expenditure of the individual authorities. Thirdly, there is the exchequer equalization grant, which is in aid of local authority finances generally and brings their resources up to a certain national average. The miscellaneous income of a local authority includes rents from local authority houses; fees, fines, and various charges; and profits from revenue-producing undertakings, such as transport services, water supply, markets, and slaughterhouses.

An interesting feature of burgh finance is the "common good," which originally formed the main revenue of burghs and usually consisted largely of property granted in the foundation charter or by subsequent gifts. Common good income can be used for anything that furthers the general good of the inhabitants or the dignity or hospitality of the burgh; it is available where there is no authority to levy a rate. Not all burghs have a common good. In 1947 all local authorities were enabled to set up "fee funds" from certain fees and commissions, which may be used in the same way as the common good.

In June 1963 the secretary of state for Scotland published a white paper on the modernization of local government (Cmd. 2067) suggesting that local government boundaries were becoming increasingly artificial and that many individual authorities were too small. The associations of local authorities agreed to enter into discussions on this and accepted, as a basis for consideration, a further report (*Reorganization of Local Government in Scotland*, HMSO, 1964) proposing a two-tier system of larger authorities. The secretary of state decided in November 1964 to review the question when an examination of the financing of local authorities had been completed.

Liquor Licensing.—The sale and supply of excisable liquor by retail is regulated under statute by separate licensing courts for counties and all but the smallest burghs, which grant certificates renewable annually for licensed hotels, public houses, restaurants, and off-license shops. Following the first report of the Committee on the Scottish Licensing Law (Cmd. 1217, 1960), the Licensing (Scotland) Act, 1962, fixed nationally the hours on weekdays during which liquor may be sold and introduced slightly shorter hours (not applying to public houses and off-license shops) on Sundays. Local "temperance" polls are occasionally held under statutory provisions dating from 1913 and may result in areas having a reduced number of licensed premises or none at all.

Civil Defense.—The secretary of state is responsible for most aspects of civil defense in Scotland, the departments chiefly concerned being the Scottish Home and Health departments for Scotland. The tasks of recruiting and training local divisions of the Civil Defense Corps are the responsibility of the local authorities. The strength of the corps in Scotland in the mid-1960s was over 30,000. For operational purposes the country is divided into east, north, and west zones, each under a zone commissioner, who acts under a Scottish central control with a senior minister in charge. Local authorities within the zones form groups for operational purposes. The Royal Observer Corps and the Monitoring and Warning Organization are organized in exactly the same way as in England, and the Civil Defense Corps is similarly used in peacetime emergencies; *e.g.*, floods. (*See* also GREAT BRITAIN: *Civil Defense.*)

2. Living Conditions.—*Housing.*—The grossly overcrowded and insanitary living conditions in the early years of the century were described in the report of the Royal Commission on Housing in Scotland in 1917. Local authorities had permissive power to build houses before then but did not build on a substantial scale until after 1919 when an act of Parliament following the royal commission's report made local authorities' housing powers obligatory and, for the first time, made exchequer housing subsidies available. Subsequent acts gave specific subsidies for slum clear-

ance and the relief of overcrowding, and under this impetus some 337,000 houses were built between the wars. About two-thirds of these were built by local authorities, with the result that the pattern of house building rapidly swung away from building by private enterprise. Subsidized council houses became a significant part of the social scene.

Private building for letting had been declining even before World War I as it became increasingly difficult to build new houses to let at rents that the working classes could afford and still give an attractive return on invested capital. The introduction of rent control in 1915 and the development of subsidized local authority houses hastened the decline; rent control was continued after the war. Private builders turned, with the aid of the rapidly developing building societies, to building for sale; but in Scotland the growth of owner occupation between the wars was much slower than in many parts of England, particularly the southeast and Midlands.

The more general government housing subsidies remained widely available to local authorities after World War II, but specific subsidies were introduced in 1957 to encourage the building of houses for overspill of population from congested areas and for incoming industrial workers. Other special subsidies that are now payable, *e.g.*, for flats in high blocks, and the increasing emphasis on slum clearance and redevelopment also reflected the need to take properly into account planning and economic, as well as social, objectives in housing policy, including the emergence of special needs of particular areas or of groups of people within the general housing problem.

Although government housing subsidies had been altered many times over the years, they were normally paid at a uniform flat rate to each housing authority. The Housing (Scotland) Act, 1962, represented an attempt to guide housing subsidies to those authorities with the greatest financial need; under the act subsidies are paid on a sliding scale according to a "resources" test that measures each authority's outgoings on housing account against its potential income.

The 1962 act also made loans available to nonprofit housing societies with the intention of widening the basis of housing provision by encouraging building by other agencies in addition to local authorities. This pilot scheme was followed, in the Housing Act, 1964, by the establishment of a housing corporation that, with the cooperation of the building societies, is intended to promote the building of houses for letting at cost rents or for group ownership, thus providing a source of housing to supplement subsidized council housing on the one hand and owner occupation on the other.

These schemes reflected the continued decline of private rented housing. Private building had remained at a low level, especially in the early years after World War II, when building control by licensing was strictly enforced. Licensing controls were, however, relaxed in 1952 and 1953 and abolished in 1954. Output by private builders has since increased but has been concentrated on building for sale, with virtually no building for letting, and private output has remained low in comparison with England.

The provision of new houses has remained the primary aim of housing policy, but the policy has been also to encourage the improvement of old substandard houses by improvement grants, which have been available since 1949 to private owners and to local authorities alike. From 1954 the policy has been to speed up the clearance and redevelopment of slum areas. Local authorities were required to submit three-year programs for dealing with unfit houses, and major slum clearance and redevelopment programs began. Glasgow presented a special problem of congestion, which could not be solved within the city itself, so that central development there had to be planned in conjunction with the movement of part of Glasgow's population to overspill reception areas in other parts of Scotland, including the new towns. Four of these, at East Kilbride, Glenrothes, Cumbernauld, and Livingston, are being developed under the New Towns Act, 1946. Moreover the Housing Act, 1964, gave local authorities power in certain circumstances to secure the compulsory improvement of whole areas of privately owned, substandard houses.

The rent restriction acts were relaxed in 1954 by allowing certain increases in the rents of privately owned houses, provided they had been kept in good repair. The Rent Act, 1957, allowed further increases in rent for houses in good repair and removed from control altogether any houses with a 1956 ratable value of more than £40, together with all new tenancies commencing after the act. A measure of protection of tenure for decontrolled tenants was restored on an interim basis by the Protection from Eviction Act, 1964.

In 1944 it had been estimated that 500,000 new houses were needed in Scotland. By 1964 more than that total had been built, the great majority by local authorities and the Scottish Special Housing Association (a body set up to assist local authorities by building in the areas of greatest need and financed by the exchequer). But the 1961 census had shown that more than a quarter of all Scottish households did not have the use of a fixed bath, while over 17% lacked exclusive use of water closet or toilet. Overcrowding had decreased as compared with 1951 but was still acute in some areas; in Glasgow 38% of all dwellings consisted of only one or two rooms, and in the whole of Scotland one-fifth of the total population lived at a density of more than 1½ persons per room. The increasing numbers of old people in the population, the trend to younger marriage, the desire to set up house independently of relatives, rising standards of living and of expectations had all increased the demand for separate houses of good quality so that despite the large output in the postwar years increased housing targets, rising to 40,000 houses a year in the second half of the 1960s, were announced. (*See* also HOUSING: *Great Britain.*)

Employment.—In recent years structural changes in the economy have had important effects on the pattern of employment in Scotland. Declining employment in agriculture and coal mining has been accompanied by contraction in the traditional manufacturing industries of iron and steel, shipbuilding, heavy engineering, and textiles, industries on which Scotland is still heavily dependent. Government action to attract new growth industries has helped provide fresh employment, particularly in the consumer durable and science based industries. Of 2,091,400 employees in employment in June 1963, the proportions in the main sectors of industry were: primary sector 8% (5% Great Britain); manufacturing 33% (38%); construction 8% (7%); public utilities 1% (2%); transport and communication 8% (7%); distribution 14% (13%); other services 26% (27%).

Unemployment.—Average annual unemployment in Scotland during the past ten years has varied between 2.4% and 3.8% but has remained at about twice the rate of Great Britain as a whole. The average rate during 1964 was 3.7%, compared with 1.7% in Great Britain. Heaviest unemployment occurs in the industrial belt of central Scotland, especially in Clydeside. There are also pockets of high unemployment in isolated rural areas, notably in the Highlands and islands.

3. Welfare and Health Services.—Formerly the relief of destitution was dealt with under the Poor Law, which in Scotland goes back to 1424. The act of a Scots Parliament in that year and other early acts, however, were largely concerned with merely restricting begging to those who could not win their living otherwise. But eventually a system of relief was developed based on the parish and administered largely by church authorities. The law was consolidated in the Poor Law (Scotland) Act of 1845, which remained on the statute book for nearly a century. Relief (or public assistance) consisted of "outdoor" relief, which was paid in cash, the recipients remaining at home; "indoor" relief, which was provided in poorhouses when a poor person required institutional care; and "medical" relief, also provided in poorhouses where hospital care was needed. The emphasis in Scotland was on outdoor rather than on indoor relief. In 1930 the administration of the Scottish Poor Law was transferred from about 875 parish councils to 55 large authorities made up of 31 county councils and 24 town councils of large burghs. Central supervision was exercised, in terms of the act of 1845, by a board whose duties eventually fell to the Department of Health for Scotland.

The breakup of the Poor Law in Scotland (as in the rest of the

United Kingdom) began with the Old Age Pension Act of 1908 and ended with the passing of the National Assistance Act of 1948. Under the latter act relief of poverty by cash payments is undertaken by the National Assistance Board, but the former public assistance authorities are required to provide residential accommodation for the aged and infirm who require care and attention. The act also empowers the authorities to provide welfare services for the blind, deaf, or dumb and other handicapped persons. There are well-established voluntary services for the elderly and for handicapped persons, and, in the exercise of their powers, local authorities commonly avail themselves of these services and assist the voluntary organizations financially.

Under the National Health Service (Scotland) Act, 1947, a comprehensive health service similar to that in England was set up (*see* SOCIAL SECURITY), which included: a full family doctor service with an associated pharmaceutical service; a general dental service; a supplementary ophthalmic service; all forms of hospital care and treatment, both inpatient and outpatient; specialist opinion and treatment; ambulance and blood transfusion services; arrangements for prevention of illness, care and aftercare, including care of mothers and young children, day nurseries, the visiting of homes by midwives, health visiting, home nursing and domestic help services, vaccination and immunization, and health education. A school health service is provided by education authorities under the Education (Scotland) Act, 1962, which consolidated earlier legislation. There are three main agencies for the administration of the health service. The general practitioner services are administered by 25 executive councils. Almost half of their members are appointed by the doctors, dentists, and pharmacists in each area, and the remainder partly by the secretary of state and partly by the local health authorities. There are five regional hospital boards responsible generally for hospital, specialist, and allied services, the actual day-to-day management of hospitals being entrusted to 79 boards of management. Regional board members are appointed by the secretary of state, and board of management members by the regional boards. The 31 county councils and 24 town councils of large burghs as local health authorities are responsible for the remaining services. All services are available to every member of the public without any insurance qualification. Charges to patients were introduced in 1951, 1952, and 1956 covering part of the cost of the general dental service, the pharmaceutical service, the supplementary ophthalmic service, and the supply of certain appliances to hospital outpatients; and for certain services, such as domestic help, local health authorities may make such charges as they consider reasonable, having regard to cost of the service and the person's means; in 1965 the Labour government abolished charges for pharmaceutical services and announced its intention to remove the other charges in due course. Otherwise the services are free of charge. The greater part of the costs is met by the exchequer. A further source of income is derived from weekly contributions under the National Health Service Contributions Acts, 1957 to 1961. Since 1959 the amount expended by local authorities on local health services has ceased to be directly grant aided but is taken into account, together with expenditure on education, child care, etc., in the general grant distributed to local authorities.

For national insurance and industrial injuries insurance services, Scotland is administered with the rest of Great Britain through the Ministry of Pensions and National Insurance. Under the National Insurance Act, 1946, which came into full operation in 1948, everyone over school-leaving age who has paid the required contributions can benefit from the scheme, which includes payments in case of unemployment, sickness, and confinement. Cover against industrial injuries and diseases arising from the nature of the employment is provided under the National Insurance (Industrial Injuries) Act, 1946. (*See* also SOCIAL SECURITY.)

4. Justice.—By the Act of Union of 1707 the legal system then existing in Scotland was preserved, and the civil and criminal jurisdiction of the Scottish courts has remained separate and distinct from that of England. The supreme civil court is the Court of Session, which is composed of 16 judges and sits in the old Parliament House in Edinburgh. It is divided into an outer house consisting of eight judges, and an inner house consisting of two divisions of four judges. Each division of the inner house sits as a court of appeal (the first presided over by the lord president and the second by the lord justice clerk) to hear appeals from the outer house or the Sheriff Court (*see* below). A right of appeal from the decision of the Court of Session normally lies to the House of Lords. The supreme criminal court of Scotland is the High Court of Justiciary, of which the judges are the same as those of the Court of Session. It sits not only in Edinburgh but also on circuit in certain cities and burghs. Trials before the High Court are always trials by jury, the Scottish jury consisting of 15 persons in criminal cases. The verdict may be returned by a majority and may in cases of reasonable doubt be one of "not proven." Since 1926 the High Court, sitting as a court of criminal appeal, has been empowered to hear appeals in certain cases tried by jury in either the High Court or the Sheriff Court. There is no appeal in criminal cases to the House of Lords. Scotland is divided for local judicial purposes into 12 sheriffdoms, for each of which the crown appoints a sheriff and a number of sheriffs substitute. The sheriffs of the county of Lanark and of the Lothians and Peebles and the sheriffs substitute throughout Scotland are whole-time resident judges presiding over the Sheriff Courts, a Scottish institution of great antiquity. The other ten sheriffs are part-time officers, chosen from among leaders of the Scottish bar. The sheriffs are mainly concerned with the hearing of appeals from their sheriffs substitute in civil cases and the performance of certain administrative duties. The Sheriff Court has a civil jurisdiction virtually concurrent with that of the Court of Session (a notable exception is that it cannot deal with divorce), and it also has a wide jurisdiction in criminal cases. Minor criminal offenses may be tried in the Burgh Police Court, presided over by magistrates appointed (except in the case of one stipendiary in Glasgow) by the town council from among their own number, or, mainly in county areas, before justices of the peace appointed by the secretary of state on the recommendation of local advisory committees.

Responsibility for the institution of criminal proceedings in the High Court and the Sheriff Court rests with the lord advocate, who is assisted in the discharge of this function by the solicitor general, four advocates-depute, and procurators fiscal stationed throughout Scotland. The crown office in Edinburgh, of which the permanent head is the crown agent, is the central department concerned with this work. Prosecutions in the Burgh and Justice of the Peace courts are instituted by prosecutors specially appointed by the town council or the justices. (*See* also SCOTS LAW.)

Police, Prisons, and Borstal Institutions.—Before 1857 the provision of police forces in Scotland was governed by adoptive acts. In that year the Police (Scotland) Act made the establishment of efficient police forces in every county compulsory. In burghs, most of which already maintained police forces, their establishment was made compulsory in 1892. The Local Government (Scotland) Act, 1929, transferred to county councils responsibility for policing all burghs other than large burghs then having their own force and limited to burghs with a population of 50,000 the right to establish their own forces in future. The Police (Scotland) Act, 1946, empowered any two or more police authorities to amalgamate their police forces and administer them by a joint committee, and it also empowered the secretary of state to amalgamate police forces compulsorily if he considered this to be in the interests of efficiency. The law relating to police administration was consolidated by the Police (Scotland) Act, 1956. There were 31 forces in Scotland in 1964, with strengths ranging from 19 to 2,729; the total establishment was 10,729. The final report of the royal commission on the police, issued in 1962, recommended some reorganization, including a reduction in the number of separate police forces and an extension of the responsibility of powers of the secretary of state. Some of the recommendations have been implemented in the Police Act, 1964. (*See* POLICE.)

Under the Prisons (Scotland) Act, 1877, the administration of prisons in Scotland was transferred from the local authorities to the state, and prison commissioners for Scotland were established. The administration passed in 1929 to the Prisons Department for Scotland and in 1939 to the Scottish Home Department.

The legislation governing the administration of prisons and Borstal institutions was consolidated under the Prisons (Scotland) Act, 1952. There are eight prisons, two of which have sections set aside for the detention of Borstal inmates, and five separate Borstal institutions, one of which has a small prison section attached. A person of 16 and under 21 years of age may be sentenced to undergo a period of Borstal training; a person of not less than 14 but under 21 may be sentenced to a term of three months in a detention centre; there are two senior detention centres for the reception of male persons aged 17 and under 21. There are no detention centres for offenders of 14 and 17 years of age and none for females of any age. The Criminal Justice (Scotland) Act, 1963, prohibited the imposition of imprisonment on any person under 21 and introduced instead a new form of detention for persons aged 17 but under 21—detention in a young offenders' institution. The first two young offenders' institutions were opened in January 1965. Young offenders may also be sent to approved schools or remand homes instead of to young offenders' institutions. *(See also* BORSTAL SYSTEM; JUVENILE DELINQUENCY; GREAT BRITAIN: *Constitution and Government.)*

5. Education.—Since 1929 the local administration of education has been a responsibility of the county councils and of the town councils of the four cities (Aberdeen, Dundee, Edinburgh, and Glasgow). The Education (Scotland) Act, 1962, which consolidated earlier Scottish educational legislation, laid on these 35 education authorities the duty of making adequate provision for educational needs and conferred on the secretary of state for Scotland powers and duties of supervision and administration, which are exercised through the Scottish Education Department.

Types of Schools.—There are three main classes of schools in Scotland, all subject to inspection: public schools, managed by education authorities (almost 95% of the total); grant-aided schools, conducted by voluntary managers who receive grants direct from the Scottish Education Department; and independent or private schools, which receive no assistance from public funds but are required to be registered. In the mid-1960s there were about 3,200 public schools, with more than 870,000 pupils, almost 50 grant-aided schools (with over 22,000 pupils), and just over 140 independent schools (with about 18,000 pupils). About one-fifth of the public schools had fewer than 25 pupils, while those with less than 100 pupils amounted to almost half the total number. Just over 700 of the public and grant-aided schools provide secondary education and, of these, almost 400 provide certificate courses extending over at least four years. Primary and secondary education is available free in public schools. The functions of education authorities include the medical inspection of school children, the provision of milk and midday meals, the conveyance of children living at a distance from school, and the award of school bursaries.

Primary education is from 5 to about 12 years of age. The Schools (Scotland) Code prescribes the broad general lines which the curriculum should follow, the framing of detailed courses being left to the school authorities, subject to the approval of her majesty's inspectors of schools. Pupils are allocated, usually between the ages of 11½ and 12½, to the various types of secondary course according to their fitness to profit from them, assessed on teachers' estimates of attainment and, in most areas, the results of verbal reasoning and attainment tests. Regard is also paid to the wishes of the parents and any exceptional circumstances. Secondary schools are of two main types: junior secondary schools providing noncertificate courses extending to three years and senior secondary schools providing certificate courses of four, five, or six years. In each type the courses are intended to provide a general education but are differentiated to suit the varying needs and abilities of the pupils; they include academic, commercial, technical, domestic, and rural courses. There are a number of comprehensive or omnibus schools in which both noncertificate and certificate courses are provided. Most schools are attended by both boys and girls. The courses in senior secondary schools normally lead to presentation for the Scottish Certificate of Education which was awarded and issued by the Scottish Education Department until 1965, when these functions passed to the Scottish Certificate of Education Examination Board. A student securing the requisite number of passes obtains exemption from the entrance examinations of Scottish and some other universities and also admission to or exemption from the examinations of a number of other professional and examining bodies. Special schools are provided by education authorities (mainly day schools) and by voluntary bodies (residential schools) for children who are physically or mentally handicapped or maladjusted. There are 26 approved schools in Scotland to which the courts under the Children and Young Persons (Scotland) Act, 1937, may send children under the age of 17 who need care and training; all but two of these schools are under voluntary management.

Further Education.—The majority of young people enter employment direct from school, most of them at the age of 15. Since 1942, those who wish to enter certain industries have in many parts of the country been given the opportunity of attending full-time prevocational courses. Once they are in employment young people may supplement practical experience by attending evening classes or part-time day-release classes. Apprenticeship training schemes are in operation in various industries. Advanced instruction in various technical and commercial subjects, in the arts, and in domestic science is provided in the colleges, known as central institutions, which are under the management of independent bodies of governors and function to a considerable extent on a regional basis. Three of these are agricultural colleges under the general administration of the Department of Agriculture and Fisheries for Scotland and the remaining ten are under that of the Scottish Education Department. Many of the central institutions award associateships or diplomas. Others present students for national diplomas, or for certificates awarded after three- and five-year courses in part-time classes. For certain courses some of the central institutions are affiliated to local universities and prepare students for degrees.

A number of people (more than 100,000) attend cultural and recreational classes for adults. Through the generosity of the 11th marquess of Lothian, Newbattle Abbey College was opened as a residential college of adult education under a representative governing body in 1937. Facilities for leisure-time occupation for young people over school age are provided largely by voluntary

associations and the churches, with assistance from education authorities, who also make some direct provision.

All teachers in public and grant-aided schools in Scotland are expected to hold one of the certificates issued by the secretary of state on successful completion of a course of professional training. Courses of training last from one to three years according to the nature of the certificate and the degree or other qualification already held.

Universities.—There are five universities in Scotland: St. Andrews (1410), Glasgow (1451), Aberdeen (1494), Edinburgh (1583), and Strathclyde (1964). By the Universities (Scotland) Act, 1858, as modified by that of 1889, the government of the four ancient universities on the academic side is entrusted to the university senate, and as regards finance and general administration to the university court. Within this framework, the University of St. Andrews, under an act of 1953, enjoys a constitution differing in some respects from those of the other universities because its teaching activities are divided between Dundee and St. Andrews. The local town councils, including Dundee in the case of St. Andrews University, are represented on university courts. The Universities acts do not apply to the University of Strathclyde, which was formed from the Royal College of Science and Technology and the Scottish College of Commerce and has a charter which lays down its constitution. Although the universities receive parliamentary grants they are autonomous with their own endowments.

The titular head of each university is the chancellor, elected for life by the general council. The office of vice-chancellor is usually held by the principal of the university, who is appointed in the case of St. Andrews, Glasgow, and Aberdeen by the crown, and in Edinburgh by a body of curators of patronage. The principal is also president of the university senate, and the rector, elected triennially by the matriculated students, is the president of the university court. In Strathclyde the chairman of the university court is elected annually by the court from among such of its members as are not members of the university's staff. The court is the supreme authority in regard to finance and the regulation of the duties of professors and lecturers. The senate consists of the principal, all the professors, and readers and lecturers specially elected, its main responsibilities being teaching and discipline. The general council, comprising the chancellor, the members of the university court, professors, lecturers and readers, and all graduates, meets twice a year to consider proposals for alteration or improvement in the arrangements of the university. In Strathclyde this function is undertaken at the annual meeting of the general convocation which comprises the chancellor, the members of the university court, and representatives from both inside and outside the university. The domestic affairs of each faculty are administered by a dean. The faculties consist of arts, science, divinity, law, medicine, engineering, and architecture.

In 1901 Andrew Carnegie founded the Carnegie Trust for the universities of Scotland, the annual income of which (about £200,000) is devoted partly to the payment of students' fees but mainly at the present day to assisting the universities in their development projects and in fostering research.

The Royal College of Surgeons, the Royal College of Physicians of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow jointly confer registerable medical qualifications. *See* also the appropriate sections of EDUCATION, HISTORY OF; ELEMENTARY EDUCATION; ADULT EDUCATION; UNIVERSITY; TEACHER TRAINING; TECHNICAL EDUCATION. (X.)

VIII. THE ECONOMY

In the middle decades of the 20th century, Scotland's population was a little over 5,000,000, or about 10% of that of the United Kingdom; almost 75% of the people live in the mid-Lowlands, compared with 50% a century earlier. Of the working population of just under 2,100,000, about 35% were in manufacturing industries, of whom half were in metals, engineering, and vehicle manufacture; 35% in distribution, administration, and professional and financial services; 16% served public utilities; and 10% were in primary production (farming, forestry, fishing, mining, etc.).

Unemployment tended persistently to be about twice the figure for the United Kingdom; the annual average unemployment percentage (1964) was 3.7 in Scotland and 1.7 in the U.K. as a whole, suggesting, it has been said, a "peripheral economy."

A. PRODUCTION

1. Agriculture.—In the mid-1960s more than 15,000,000 of Scotland's 19,069,568 ac. (7,717,454 ha.) were used for agriculture, but over two-thirds were in rough grazing, only 883,000 ac. (357,350 ha.) in permanent grass, and just under 3,500,000 ac. (1,416,450 ha.) in arable (almost 50% in temporary grass, 25% under oats, mainly for fodder, and the rest under fodder crops, *e.g.*, turnips, or cash crops, *e.g.*, potatoes, wheat, barley). Cattle totaled over 1,989,000, all attested as free from bovine tuberculosis (incoming animals being subject to control). Dairy cattle were mainly Ayrshire and British Friesian; beef cattle included Aberdeen Angus, Shorthorn, Galloway, and West Highland or Kyloe, along with various crosses. About 8,500,000 sheep included Blackface (on heathery hills), South Country and North Country Cheviots (on grassy hills), and Border Leicester, Suffolk Downs, and other English breeds (on Lowland farms), as well as crosses with hill sheep. Pigs numbered 439,000 and were of growing importance; poultry, totaling almost 8,500,000, were of particular importance to small farmers in the counties of Aberdeen and Orkney; production in the artificial environment of battery and deep litter houses is increasing in importance. About 61,000 recorded agricultural holdings included some comprising several farms; about 28,000 were regarded as full-time holdings (over 30 ac.; 12 ha.); the rest, crofts and other small holdings, provided only part-time occupation to the holders. The main regional types of farming are: (1) arable stock farming in the eastern Lowlands, often on large farms, sometimes with important cash cropping (potatoes, wheat, barley, and locally sugar beet); (2) dairying, largely based on arable with temporary grass, often on small to medium-sized family farms, on the Lowlands and the lower plateaus in the southwest and the western mid-Lowlands, and spreading elsewhere; (3) hill-sheep and cattle-rearing farms, often large units operating on very poor land, in the Southern Uplands and in the Highlands, where they are also run by crofters and other small holders.

The present state of farming in Scotland owes much to the agricultural revolution effected mainly during the 18th century. There was a great gain in technical efficiency and a general rise in standards of living. Early in the 18th century an almost medieval runrig or rundale open-field system was seen in decadence, with many signs of imminent collapse. This type of open-field system generally consisted of a constantly cultivated infield periodically subdivided into a number of strips according to the needs of the community, and of intermittently cultivated outfields periodically left fallow or brought under the plow by communal decision and effort and similarly divided into strip fields by lot. It is certain that in decadence there was fragmentation of individually held strips, which contributed to the eventual breakdown of the system. Agricultural improvements lagged behind those taking place in England, save for patchy, piecemeal changes by individual improvers, and standards of living were generally poor. By 1800, and certainly by the end of the Napoleonic Wars, which accelerated the changes, the more productive Lowland areas had been largely enclosed and improved, creating landscapes ancestral to those of today, with estates or mansion, park, and wood, and substantial tenant farms with large rectangular fields, hedged, fenced, or walled. Farmsteads and workers' cottages were sited as centrally as possible amid the fields and commonly some distance from villages, which supplied service functions and a little small-scale manufacturing but took little direct part in the farming.

In the Highlands comparable enclosures followed the breakup of the runrig system, strained by population increase in a harsh physical environment. The notorious Highland clearances, probably inevitable but too often brutal in execution, took place in the century following the Jacobite rising of 1745. Many peasant farmers found themselves landless as land was taken over for sheepwalks or enclosed into larger farm holdings. Related events were the abolition of heritable jurisdictions (a hallmark of the clan system), the pacification of the Highlands, the building of

FIG. 3.—MAJOR AGRICULTURAL AREAS OF SCOTLAND

military roads, the coming of a cash economy, and landlordship on the English model. These changes left the landscape much as we now see it, with sporting estates and mansions, large sheep farms divided into hirsels (each in the charge of a single shepherd often living in an isolated cottage), and, in contrast, the often overcrowded crofting townships. These settlements were groups of cottages each with individual strips of arable and improved land, which were open to the township as a whole for winter grazing, and rights were held to common grazing on the hill land. The crofting problem was complicated by the famine of 1846–48 and by the continual emigration of young people to industrial Britain and overseas. This trend continued into the 20th century, despite the reforming acts of 1886 and later years, which brought security of tenure, fixed rents, enlarged holdings, improved cattle breeding, roads and piers, home industries, and the resettlement of some families on estates bought by the government. The Crofters (Scotland) Act of 1955 encouraged reorganization of holdings for greater efficiency, with assistance by special grants, while a permanent Crofters Commission was set up to speed and smooth negotiations for such a reorganization and had powers to control the reletting of crofts and to terminate the tenancies of absentee crofters. Concurrently, several other forms of development have improved conditions locally: Forestry Commission plantations; a fish-curing plant; hydroelectric projects and aluminum refineries at Kinlochleven and Lochaber, near Fort William; harvesting and processing of seaweed; a renewal of interest in cattle rearing on hill land, publicized as cattle ranching; a newsprint factory in the Fort William area; various experiments in small-scale manufacturing; and some increase in catering for tourists.

In Scotland as a whole the Napoleonic Wars not only speeded agricultural change but also increased industry, commerce, and facilities for agricultural finance and marketing. The mid-Lowlands region was especially affected and was transformed from an underdeveloped to a highly developed part of Britain. With peace came more difficult times for farmers, with the competition of increased trade from overseas, and strain and restlessness among their workers. With the flood of overseas cereals in the late 19th century came more widespread changes: decreased extent of tillage; increased grass and stock; marked rural depopulation; the breaking up of some estates, coupled with an increase of owner-occupied farms and of working, as against gentlemen, farmers, although technical standards remained high. The early 20th century saw the spread of formalized agricultural education, the intensive farming effort of World War I, the boom in food crops; then, with peace, harder times again for farming, the establishment of new agricultural research organizations, and the purchase of estates by the government to set up small holdings to give needed opportunities to the younger generation and especially to ambitious farm workers. Following the general economic slump of the 1930s came government subsidies on wheat (1932), barley and oats (1937), and on beef. World War II brought guaranteed prices and assured markets for the chief products; subsidies for plowing up land, fertilizers, and reseeding grassland; intensified advisory services; and, for a time, emergency powers of control over, and even ejection of, inefficient farmers. After the war came new expansion programs (1947 and 1952). Legislation dealt with production and marketing and the fixing of minimum and overtime wages, and hill farming (1946), livestock rearing (1951), and security of tenure for tenant farmers (1949). The government makes an annual review of agriculture, then fixes guaranteed prices for cattle, sheep, pigs, milk, eggs, wheat, barley, oats, rye, potatoes, sugar beets, and wool. Grants or subsidies are available for plowing up marginal land, drainage, water supplies, bracken eradication, farm cheese making, and the raising of hill sheep, hill cattle, calves, and attested herds.

2. Forestry.—From a predominantly wooded landscape, deforestation at several phases of history had produced an almost treeless landscape by 1800. Landowners' reafforestation, amenity woodlands, and shelter belts, along with scrub oak and birch, exceeded 1,000,000 ac. (about 405,000 ha.) by 1900, but World War I brought widespread felling of useful timber. The Forestry Commission, set up in 1919, established many plantations, which unfortunately had not matured by World War II, and further reduction of reserves of standing timber resulted. Of the target of a national planting scheme (1946) of 5,000,000 ac. (2,023,500 ha.) of productive woodland on private and Forestry Commission land to be realized by the end of the century, at least half was to be in Scotland. In the mid-1960s private woodland totaled about 470,000 ac. (190,000 ha.); commission-owned woodland totaled about 660,000 ac. (267,000 ha.), employing just under 4,000 people. The commission buys estates for planting, mainly with Scots and Corsican pine, Sitka and Norway spruce, European, Japanese, and hybrid larches, and Douglas fir, according to the particular site. Since 1945 policy has been notably broad based, including agricultural interests, and in the late 1950s the emphasis switched from the strategic importance of timber production to the significance of its role in the development of integrated land use. This trend continued into the 1960s. Farmers use pastures above the forests in conjunction with improved low-lying fields, sometimes in forestry holdings (where the farmer agrees to carry out and is guaranteed at least 150 days' forestry work per annum). The social aspects also are now stressed. Rehabilitation of depopulated communities has been achieved, so that new schools and better services can economically serve the increased population; new villages have been formed and National Forest parks (Argyll, 58,000 ac.) demarcated.

3. Mining.—Coal is the chief mineral resource. Mining rights were granted in a 12th-century charter to William Oldbridge of Carriden, West Lothian, and in 1291 to the abbot and convent of Dunfermline, but coal was not widely used in houses until the late 16th century, when coal exports were beginning to be important. The Industrial Revolution brought great expansion for both export and internal use in homes and factories. By 1910–13 Scotland was producing around 15% of the United Kingdom's total output, but the 1920s brought loss of overseas markets, lower domestic demands because of the general slump, industrial unrest, and competition from other fuels. In 1939 production was 30,500,-

000 tons, falling to 21,400,000 in 1945—about 10% of the U.K. total—mined by 12% of the mining manpower. Nationalization in 1946 brought surveys of the problems, and in 1950 the National Coal Board's (NCB) plan for coal (for Great Britain). The Scottish coalfields incur high running cost because of the presence of steep folding, volcanic intrusions, thin seams, and excessive water. These conditions are marked in the central field on which so much heavy industry was based, and output has decreased. This decline, coupled with expansion in the eastern fields of Fife and Midlothian, raised social and economic problems reaching beyond the industry. But by 1960 overproduction had succeeded shortages, owing largely to competition from oil, and the NCB's plan was revised.

In Scotland coal of economic importance occurs in the Limestone Coal Group and in the Productive Coal Measures. The main coalfields' resources, current development, and problems may be summarized as follows. In the coalfield of the East Fife-Midlothian syncline the steep beds of western Midlothian and around Kelty and Lochgelly in Fife are largely exhausted; but there are large new mines and reserves in the flatter beds, including the deep Limestone Coal Group farther east, around Dalkeith in Midlothian, and the new town of Glenrothes in Fife. However, at Glenrothes unforeseen technical difficulties underground have brought a premature end to a major development project, but development of the town is continuing with associated light industry. Coal from this field is mainly highly volatile, weakly coking, or noncoking, in seams three to six feet (one to two metres) thick, probably with large reserves under the Firth of Forth. In the West Fife-Clackmannan syncline the coal is similar, the main reserves lying in the eastern flank. This field continues under the Forth into the declining but historically important central field lying mainly in the county of Lanark. There the thick upper coals of the Productive Coal Measures are almost exhausted and the remainder too thin or rendered dangerous by water from old workings, while the Limestone Coal Group, deep under the Productive Coal Measures and the Millstone Grit, is not exploitable at present. A factor that has contributed to the decline of the central field is the mid-20th-century tendency to close the small, old, inefficient pits and to open larger modern ones, mainly sited in the east, where the main reserves are found at depth, especially extending from Stirling under the Forth. There are, however, accessible seams and considerable reserves in a belt from northeastern Glasgow to Denny, and appreciable output of anthracite, special coals, and some strongly and medium-coking coals, which, mixed with Durham coking coal, are very important to the Scottish steel industry. Therefore, demand may call for considerable capital expenditure to exploit the known reserves. In the Ayr and Dumfries field weakly coking and noncoking coals are declining in the central area, with expansion on the margins and considerable reserves under the Permian rocks in the Mauchline Basin.

4. Fisheries.—Fishing is more important proportionally in Scotland than in the United Kingdom as a whole, but there has been a steady decline in the number of fishermen. In the mid-1960s there were just under 3,000 Scottish vessels, including about 160 steam and motor trawlers, with over 10,500 fishermen, of whom roughly one-quarter were part-time and crofter fishermen. Landings by British and foreign vessels exceeded 6,000,000 cwt. (305,000 metric tons), principally haddock, cod, whiting, skate, plaice, herring, mackerel, sprat, and shellfish (lobster, crab). Landings are greatest in the Aberdeen fishery district, well ahead of Leith, Fraserburgh, Lossiemouth, Peterhead, and Buckie on the east coast, Loch Broom, Ayr, Oban, Stornoway, and Campbeltown on the west coast, and Orkney and Shetland. Salmon and sea-trout angling is an important tourist attraction, while in 1963 netting employed over 1,600 men in the season, with a catch of 1,900 tons, including about 350 tons by rod and line.

There are government fishery officers at ports and on fishery cruisers; research stations at Aberdeen and (for fresh water) at Pitlochry; the head office of the United Kingdom Herring Industry Board; and a committee of the White Fish Authority for Scotland and Northern Ireland. Current trends include a change from steam to motor vessels, with grants for new vessels or for conversion from coal to oil, and a scheme for the encouragement of full-time fishing in the Outer Hebrides.

5. Power.—Electricity is distributed by two public boards responsible to the secretary of state for Scotland. The North of Scotland Hydroelectric Board (1943), employing over 3,000 people, operates over the area roughly north and west of the Firths of Clyde and Tay; the South of Scotland Electricity Board (1954), employing about 12,500, operates over the remainder of the country. Electricity is generated by steam using coal, oil, or atomic energy, by waterpower, sometimes by diesel engines, and experimentally by gas turbines, including the plant using peat at Altrabreac.

There has been a great mid-20th-century drive to develop the hydroelectric power potential of the Scottish Highlands. The aim has been to supply power to all the farms and crofts, stimulate industrial development, indirectly increase agricultural production, and generally stem the emigration of the rural population from the Highlands. The heavy rainfall in this area and high incidence of ribbon lakes, which act as reservoirs, are great advantages for hydroelectric development; but most large lakes are relatively low in altitude, streams are variable in volume, and catchment areas are often small so that tunnels must be excavated through watersheds to increase the drainage into the reservoirs. In this way, the natural catchment area (6½ sq.mi.; 17 sq.km.) of Loch Sloy was increased to 31 sq.mi. (80 sq.km.); the water dammed back in Loch Sloy Reservoir travels 2 mi. (3 km.) by tunnel through Ben Vorlich to the power station (1950) on Loch Lomond. The larger Highland schemes, of which Loch Sloy is an example, contribute electricity to the grid system in central Scotland. The Tummel-Garry scheme and the Mullardoch-Fasnakyle-Affric scheme are similar, and both involve the construction of tunnels to increase the catchment areas. Smaller schemes, such as Glen Lussa and Morar, supply the needs of the local population. In the mid-1960s only about 10% of Scotland's potential had been realized: capital costs of construction are high and would presumably be higher as less easily exploitable sources were tapped, and on current costing thermal power is a little cheaper.

Scotland shares with the rest of the U.K. in the development of nuclear power stations. In the mid-1960s three were functioning: Dounreay fast-breeder reactor station; Chapelcross, associated with a plutonium factory; and Hunterston station.

The Scottish Gas Board in the mid-1960s employed about 9,500 people at over 100 works, producing 41,000,000,000 cu.ft. (1,161,000,000 cu.m.) of gas (84% coal gas, 15% water gas). Trends since nationalization in 1949 have included the closing of about 100 small gasworks as supplies became available from larger, more economical works by linkage mains. In the early 1960s a Lurgi high-pressure complete gasification plant at Westfield, Fife, marked the beginning of a supergrid system for the mid-Lowlands, designed to link with local grid systems.

6. Industries.—To understand the problems of Scotland's economy as a whole, it is necessary to look at it, and at industry in particular, from the historical viewpoint. The Scots Parliament's last few years were far from inactive in economic affairs, yet at the Union of Parliaments (1707) the economy was still largely medieval, and in decadence as a result of the wars of independence, involvement in the struggle for power between France and England, and the religious wars (from the late 13th to the late 16th centuries), and latterly of several famines between 1695 and 1702, and the halting of projects for economic improvement after the disaster of the largest, the Darién scheme (1695–1700), which was partly caused by English opposition. In 1707 Scotland was in no position to take advantage of the new access to the markets of England and the colonies. But by 1750 trade was flowing: for a time Glasgow merchants had a near monopoly of the Virginia tobacco trade and also joined in the slave trade, thus encouraging developments in agriculture and banking. The latter had unique features adapted to a poor country in which capital grew largely through reliance on borrowers' and guarantors' moral character, and in consonance with current religious thought. As the Industrial Revolution began to affect textiles, Scotland was well placed, with its large flax and linen hand-spinning and weaving industries

(the encouragement of which followed the Union and was the original function of the British Linen Bank), its large supplies of pure water, and many waterfalls useful in the waterpower phase. Linen factories, followed by cotton, became widespread, especially in the mid-Lowlands. With the introduction of coal-based steam power and more centralized factories, sites near the mid-Lowlands coalfields were favoured, and the linen industry had vigorous survivors up to the 1960s, notably in Fife and Angus, and also added the daughter industry, jute. Woolen factories for spinning, weaving, and knitwear, often high-grade or luxury goods, are found in many of the larger Scottish towns, being particularly important in the Border country, and handloom Harris tweeds are an important export commodity from the Hebrides. Paisley is a prominent centre for the cotton industry; there are also about 30 cotton factories (including two survivors from the 18th century at Doune in Perth and Catrine in Ayr).

The early dominance of the textile industry was followed by a decline initiated by the dislocation of the American Civil War of 1861–65, leaving Lancashire henceforth dominant in Britain's cotton industry. Displaced capital tended to move toward heavy industries, iron and steel, heavy engineering, and shipbuilding, which were to dominate a second phase of the Industrial Revolution in Scotland, felt notably in the mid-Lowlands. Glasgow became the principal centre in commerce, shipping, coal mining, textiles, chemicals, and engineering, which has now evolved into the great Clydeside conurbation. The discovery of how to use blackband ironstone both as a fuel and an ore, Neilson's hot-blast steel plant (1828), Naysmyth's steam hammer (1825), the coming of railways from 1830 on, steam propulsion in ships (William Symington in 1802, Robert Fulton in 1803, and Henry Bell in 1812), the building of ships of iron and, later in the century, of steel, all marked a phase of inventiveness, confidence, and increasing industrial development. The Clyde became and remains one of the world's major shipbuilding districts, and there were smaller but locally important shipyards on the east coast (Aberdeen, Dundee, and Leith), and engineering there and in many other towns. The Clydeside industrial complex has persisted despite the decline in coal output from the central field and the fact that the blackband iron ores, on which the iron industry was originally based, are little worked, having been replaced by imported ores. The Clyde Valley is one of the major steel-producing regions in Britain. Heavy steel products are typical, and only about a fifth of the total output is exported, as Scottish production is oriented to the home demand of the major, essentially heavy industries, notably shipbuilding, marine engineering, and boilermaking.

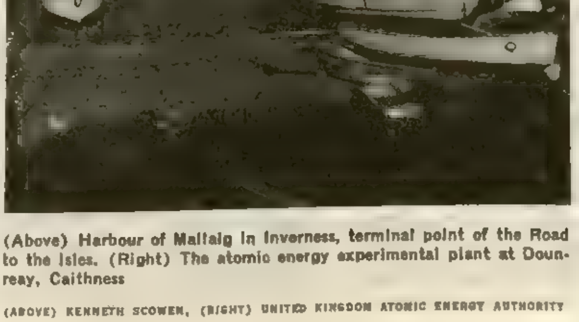
The depression of the early 1930s brought unemployment throughout the country for about one worker in ten; the unemployment ratio was considerably worse in the heavy industrial areas (since known successively as depressed areas, special areas, and development areas). This situation emphasized the need to diversify Scotland's economy and gave rise to a drive to increase the country's participation in the manufacture of automobiles, aircraft, radio, electrical apparatus, and modern light engineering and mass production industries. Special advisory bodies were set up, now consolidated as the Scottish Council (Development and Industry). Scotland's first industrial estate, Hillington, in the county of Renfrew, was opened in 1938, and by 1939 there were 70 factories, including a Rolls-Royce aero-engine factory. By the mid-1960s more than 20 industrial estates and 30 individual new plants of converted armaments works housed over 350 industrial tenants on an average floor space of over 40,000 sq.ft. (3,700 sq.m.). Products included tractors, earth-moving and agricultural machines, typewriters, computers, refrigerators, and other electrical and electronic apparatus (the last fostered by special research facilities), watches and clocks, textiles and clothing, and numerous food products.

Car manufacturing is once more carried out in Scotland by branch factories of firms of the English Midlands, encouraged by the government to move new production developments to central Scotland. Exports are substantial, and Scotland has attracted over 60% of those United States firms that have set up factories in Britain since World War II. Despite all these developments, however, the traditional heavy industries persist as the basis of Scotland's economy. Shipbuilding remains at a high level, even if lower relative to world production and latterly with a serious falling off in new orders. Major reorganization and reconstruction in the steel industry broadly favours traditional sites. In exports textiles, whisky, and the newer industrial estate products all play a vital part. Yet up to the 1960s unemployment persisted at a higher level than in England. There is growing conviction, indeed growing evidence, that in certain respects Scotland's economy is merely peripheral to the main flow of prosperity in Britain. Yet, as Scottish nationalists point out, Scotland is not lacking in resources. It is more nearly self-supporting in food than England and its farming less dependent on imported fodder. In industry the relative lack of experience in, and concentration on, mass production may prove a less grave disadvantage as automation increases. Twenty years' real achievement and experience provided material for a review of Scottish industry, which was undertaken in the 1960s by the Scottish Council. (A. T. A. L.)

7. Banking.—The monopoly granted to Scotland's first bank, the Bank of Scotland, was not renewed when it expired in 1715. The resulting freedom to issue notes, which in those days was synonymous with banking, made possible the formation of large banks and the spread of branches throughout the country. As a result, the provision of banking services had been concentrated in the hands of a few relatively large and stable institutions even before 1844, when the Bank Charter Act began the process of absorption and amalgamation among the small country banks in England.

The Scottish banks still retain the right of note issue, but the Bank Notes (Scotland) Act, 1845, obliged them to hold gold coins as cover against notes actually in circulation in excess of a stated maximum, which has not since been increased and now forms a very small proportion of the total circulation of the banks. With the withdrawal in the 20th century of gold coin from the country's currency, Bank of England notes became the principal covering requirement. These issues, however, still make it possible to maintain branches in small communities where, without them, the provision of banking services would be too expensive.

The following banks now operate in Scotland: Bank of Scotland



(Above) Harbour of Mallaig in Inverness, terminal point of the Road to the Isles. (Right) The atomic energy experimental plant at Dounreay, Caithness

(ABOVE) KENNETH SCOWEN, (RIGHT) UNITED KINGDOM ATOMIC ENERGY AUTHORITY

(1695), Royal Bank of Scotland (1727), British Linen Bank (1746), National Commercial Bank of Scotland Ltd. (1810), and Clydesdale Bank Ltd. (1838). (X.)

B. Transport and Communications

1. Roads.—Roads are classified as trunk roads, a responsibility of the secretary of state for Scotland, about 1,950 mi.; and as Class I, 4,800 mi., Class II, 3,900 mi., Class III, 6,300 mi., unclassified, 11,400 mi., all these being the responsibility of local authorities (mainly counties since 1929). In 1963 work began on a motorway between Glasgow and Edinburgh. The network comprises: (1) the mid-Lowlands, dense, well surfaced, in places overcrowded, with a close, largely radial pattern around Glasgow, and a persisting concentration of routes through Edinburgh's Lowland gap; (2) the Southern Uplands, a much wider pattern, though still well surfaced; in lower Tweeddale a fairly close network; (3) east of the Highlands, dense and well surfaced around Aberdeen, linking with good east coast routes, with central Grampian routes (Glen Shee-Devil's Elbow; Glen Garry-Strathspey). Beyond single strands follow glens to the west coast, sometimes single lane only, with passing places; minor roads are poorly surfaced. In the southwest Highlands, the roads Loch Fyne-Oban and Glasgow-Loch Lomond-Glencoe-Fort William are spectacular.

The mid-Lowlands firths are a considerable barrier; the Forth has a bridge at Kincardine and another at Queensferry (completed 1964); the Firth of Clyde as yet has no road bridges, though two tunnels were constructed at Whiteinch in the early 1960s to relieve congestion on ferries and Glasgow's bridges; a bridge across the Firth of Tay was scheduled to be completed by 1966. The present pattern is largely the legacy of the 18th century turnpike acts, with minor roads long maintained under earlier statute labour acts, and of military road building in the Highlands by General George Wade and others.

2. Railways.—Administered under the Scottish Region of British Railways since 1947, Scottish railways include: (1) in the mid-Lowlands a close network, especially around Glasgow, with more east-west lines than elsewhere, those between main centres bearing heavy traffic; (2) in the Southern Uplands a looser mesh, including busy main lines from Glasgow and Edinburgh to the south seeking low crossings (Beattock, the highest, 1,028 ft. [313 m.]); (3) in the north, continuous lines up the east coast Lowland to Wick and Thurso, complemented by the Perth-Inverness route through Drumochter Pass (1,500 ft.; 457 m.) and lines southwest from Dingwall to Kyle of Lochalsh on the west coast, Stirling-Oban and Glasgow-Mallaig, all to small Highland ports.

In the 18th century horse trams took coal downhill from pithead to port; the first act authorizing such a horse railway (Kilmarnock-Troon) was in 1812, and the 191¼ mi. of line was approved by Parliament in 1840. This was followed by rapid development and consolidation into the North British Railway (1845, mainly on the east coast), the Caledonian (1845, mainly west and central), the Great North of Scotland (1846, mainly around Aberdeen), the Glasgow and South Western (1850, sharing the Clyde sailings with the Caledonian and North British), and the Highland (1865). The Railway Act of 1921 amalgamated these private lines into two groups: the London, Midland and Scottish; and the London and North Eastern railway companies, until nationalization in 1947. As elsewhere the 1950s–60s saw the closing of many branch passenger lines and more frequent services on remaining lines, using diesel to replace steam engines.

3. Shipping and Canals.—The principal ports are Glasgow, a major port of the United Kingdom, Leith, Grangemouth, Dundee, Greenock, Aberdeen, Ardrossan, and Methil. The ports are mainly on the firths penetrating the richer mid-Lowlands region. The east coast ports were more important in the 15th to 17th centuries, but the west coast gained with the increase in Atlantic trade and the industrial development of the Glasgow area.

The British Transport Commission owns and operates the Caledonian Canal, the Crinan Canal, and the Forth and Clyde Canal. They are economically unimportant, mainly carrying relatively small quantities of coal, coke, and liquid fuel; all run at a deficit. The Monkland and Union canals, now closed to navigation, are maintained for industrial water supplies and are operated at a small profit.

4. Air Services.—Prestwick is an international airport (controlled by the minister of transport and civil aviation) used by most airlines with North Atlantic services and connected with several European capitals. It was developed by Scottish Aviation Ltd. and taken over and developed further by the Air Ministry during World War II; in the early 1960s it was extended to accommodate large jet aircraft. In British European Airways' (BEA) internal services, Renfrew is the main base for Campbeltown, Islay, Tiree, Barra, Benbecula, and Stornoway; Aberdeen and Wick serve Orkney and Shetland, and Edinburgh and Inverness are included in the network. Renfrew and Edinburgh have services to London and the south.

Commercial civil aviation began in the 1930s (Inverness-Wick-Kirkwall, 1934; Newcastle-Aberdeen-Stavanger, 1937). By 1939 the framework of the present system was based on Renfrew and Aberdeen, with an early and fine tradition of an ambulance service bringing urgent cases from remote landing strips to Renfrew, Inverness, Aberdeen, and Wick. This service is still maintained by BEA and augmented in emergency by Royal Navy and Royal Air Force helicopters. Future developments may include a more economical scale of service, to enable still more remote areas to benefit from air transport.

5. Postal and Telecommunications Services.—These services are integrated with those of the rest of the United Kingdom (*see* Great Britain and Northern Ireland: *Transport and Communications: The Post Office*). Postal services are maintained in Scotland by head post offices in the main cities and post and sub-post offices throughout the rest of the country. Of the telegram and telephone services, the former is receding in use and constant availability as the latter becomes more widespread. The main flow of telephone calls is between the main cities of central Scotland, with busy trunk lines from Glasgow and Edinburgh to the Midlands of England and to London. However, automatic and subscriber trunk dialing already extends to quite small rural exchanges. In the mid-1960s, 5 of the Shetland Islands, 6 of the Orkneys, and 15 of the Western Islands were served by radio-telephone.

The country is covered by national and regional sound radio services of the British Broadcasting Corporation; truly local broadcasting is as yet in its infancy. Scotland also has a television network of BBC and commercial transmitters. (A. T. A. L.)

SCOTLAND, CHURCH OF. The Church of Scotland claims to be "part of the Holy Catholic or Universal Church," reformed in the 16th century but continuous with the church of the apostles. This article outlines its history and indicates its position in the national life. It is established by law in Scotland and its polity is Presbyterian. (*See* further SCOTLAND: *History*; PRESBYTERIANISM.)

Early Period.—Christianity was first brought to what is now southwest Scotland during the last years of the Roman occupation of Britain. According to tradition, St. Ninian, a Briton by birth but trained on the continent of Europe, founded a church at Whithorn (*c.* 400) and did missionary work beyond the sphere of Roman influence. The next great name is that of St. Columba, who settled at Iona *c.* 563. He was only one of many missionaries from Ireland at that period, and there is controversy as to how much of the Christianizing of the country is due to him, to them, or to Ninian and his successors. At all events the church in Scotland until the 12th century was the church in its Celtic form (*see* CELTIC CHURCH), affected by influences from the Roman Church in England but cherishing its native customs, partly in opposition to external pressure and partly because for generations Scotland was comparatively isolated by the raids and settlements of the pagan Norsemen.

The Medieval Church.—The assimilation of this church to the general pattern of the church of the West was part of a change which came over Scotland when its kings in the first half of the 12th century formed their kingdom after the fashion of the Anglo-Norman kingdom of England. The rudiments of parochial and diocesan organization were greatly developed, and monastic orders from England and the continent were introduced and lavishly endowed, especially by David I (*q.v.*). There was as yet no Scottish metropolitan, and the English archbishops of Canterbury and of York, particularly the latter, claimed that the Scottish bishops were subject to them. In 1192, however, the Scottish church was declared "a special daughter" of the Roman see, subject only to the pope. Not until 1472 did St. Andrews become an archiepiscopal see, followed by Glasgow in 1492.

During the medieval period the church in Scotland shared in the features common to the Western Church as a whole. It derived stimulus from monastic revivals and the coming of the friars: the universities of St. Andrews, Glasgow, and Aberdeen were founded in the 15th century: its outstanding figures were statesmen as well as clergy, and though little is certain about its education, its theology, or its devotional life there is evidence that these were far from negligible and that the medieval church in Scotland preserved the essentials of Christian faith and practice, however much these were entangled with notions and customs that were rejected at the Reformation (*see* REFORMATION: *Scotland*).

The medieval church had glaring defects. About 85% of its parishes were "appropriated" to cathedrals, bishoprics, abbeys, and other institutions, with the result that the bulk of the parochial revenues went to these higher levels, leaving a pittance for the vicar who did the parochial work. Another abuse was the violation of church discipline through scandalous appointments to high office in the church. Responsibility for this lies chiefly on the

crown, but the connivance of the papacy cannot be ignored. The statutes of the Scottish provincial council in the decade before the Reformation are evidence for the abuses that abounded; but they also testify to the existence of a body of opinion favourable to moderate reform.

The Reformation and After.—Had there been a strong monarchy in Scotland the outcome might have been a reformation like that in England or in Scandinavia. The Scottish crown, however, weakened by a succession of royal minorities, passed in 1542 to the infant Mary, queen of Scots, who was sent to France and betrothed to the dauphin, later Francis II, and from 1554 Scotland was governed by her mother, a Frenchwoman, Mary of Lorraine. The Scottish Reformation therefore was in large part a national movement for Scottish independence against the domination of France, and at the same time a revolution in opposition to the crown.

The earliest Scottish reformers, such as Patrick Hamilton, were under Lutheran influence. George Wishart made contact with the Swiss reformers, but the Calvinistic tone of the Scottish Reformation was due to John Knox (*q.v.*). Knox's admiration for Calvin and Geneva is evident in his Scots Confession, in the Book of Common Order, often known as Knox's Liturgy (*see* Common Order, Book of), and in the Book of Discipline (later called First Book of Discipline) which set out a scheme for a godly church and commonwealth. The Reformers held a Parliament in August 1560 which abolished the authority of the pope in Scotland, adopted the Scots Confession, and forbade the celebration of Mass. The First Book of Discipline, which included a plan for education and the care of the poor, presupposed the handling by the Reformed church of the great wealth of the medieval church. This was abhorrent to the nobility and gentry, who in various ways had obtained control of much of the church's wealth even before 1560, and was never approved by Parliament. Although the absent queen Mary Stuart sanctioned the meeting of Parliament, the religious question was reserved, and this legislation, never confirmed by her, was ratified by the regent in the name of her infant son, James VI, after her abdication in 1567.

After the breach with Rome there followed a century and a quarter during which it was uncertain whether the Reformed church was to be episcopalian or presbyterian in government. The Reformers recognized no order superior to the ministry of the Word and sacraments, but episcopacy was not a vital issue in the Reformation. Four of the Scottish bishops in 1560 supported the change and three of them continued to serve under the General Assembly, a body partly clerical partly lay, while five superintendents were also appointed. After the abdication of the queen an act was passed giving the superintendents authority to admit men to benefices, which meant in practice that when the Romanist holders of benefices died each was succeeded by a minister of the Reformed church. Similarly, by the Concordat of Leith (1572) ministers were to be appointed to the bishoprics. They were to have the same powers as superintendents and be subject to the General Assembly. Nomination of these bishops lay with the crown. This concordat was accepted by the General Assembly only as an interim measure. Nevertheless it was accepted, even by John Knox, and it was not till after his death (1572) and after Andrew Melville (*q.v.*) returned to Scotland from Geneva in 1574 that controversy broke out.

Melville, not Knox, should be called the originator of Scottish Presbyterianism, for it was he who converted many Scottish churchmen to the view that the bishop in the New Testament was the pastor of a particular congregation having no authority over other ministers, so the functions of supervision should no longer be exercised by bishops or superintendents, but should be taken over by a body called a presbytery, composed of ministers and elders. Eventually this view was approved, and a beginning was made in 1581 when 13 presbyteries in the Lowlands were organized. King James VI, however, was determined that bishops should rule the church and that he should appoint and rule them. The struggle was long and keen between the divine right of presbytery and the divine right of kings. At first the king had to yield from time to time. In 1592 he was compelled to assent to an act which gave parliamentary sanction to the system of presbyterian courts. Yet there were still parts of the country where ministers and kirk sessions and presbyteries were lacking, and the act left the king a measure of control over the church, for it reserved to the crown the right to appoint the time and place for the meeting of General Assemblies. From that time the king's policy steadily advanced, and after he had become James I of England he secured most of what he wanted. By 1610 he had persuaded the General Assembly to accept bishops who should indeed be subject to its censure but have a real authority in their dioceses, and for them he secured consecration at the hands of English bishops. No doubt his intention was that in time presbyteries and General Assemblies should be allowed to lapse.

The story of the ecclesiastical policy of Charles I and later kings, and the opposition to it which found expression in the covenants and the resultant civil war and persecutions, is long and complicated. Briefly, there were two periods, 1610–38 and 1661–89, when the Stuart kings were successful in imposing episcopal government on the lower presbyterian courts. At the end of each period, the final rejection of episcopacy was primarily due to its identification with royal absolutism in church and state and with a hankering after Roman Catholicism. Under pressure from the Scottish Parliament, William of Orange agreed not only to the abolition of episcopal government as "contrary to the inclinations of the generality of the people ever since the Reformation" but also in 1690 to the establishment of presbyterian church government, "that is to say the government of this Church by kirk-sessions, presbyteries, provincial synods and general assemblies," and to the ratification of the Westminster Confession (*q.v.*), which had been approved by the General Assembly in 1647. Nothing was said of the divine right of presbytery or of the perpetual obligation of the covenants of 1638 and 1643 whereby the Scottish Presbyterians had pledged themselves to uphold their own ecclesiastical system (*see* Covenanters). For that reason the extreme Covenanters remained outside the established church, Presbyterian though it was, as the convinced Episcopalians and Roman Catholics did for other reasons.

18th Century.—An act for securing the Protestant religion and Presbyterian church government was included in the Treaty of Union in 1707 (*see* English History), but five years later the united Parliament in London passed an act for the restoration of patronage in Scotland, which, although not the cause of, was an important factor in, the troubles which issued in the First Secession of 1733 under Ebenezer Erskine and in the Second Secession of 1761 under Thomas Gillespie, founder of the Relief Presbytery (*see* Presbyterianism). Another factor was the difference of policy and outlook between the two parties in the church which came to be known as Moderates and Evangelicals. Moderatism was the Scottish version of what is commonly known elsewhere as the Enlightenment. In reaction from religious wars and persecutions, men everywhere saw the virtue of tolerance and benevolence. Fanaticism was to be repudiated and everything brought to the bar of reason. The application of such ideas to religion did not necessarily lead to heresy, but it minimized the distinctively Christian affirmations in the sphere of doctrine and laid a greater emphasis on moral teaching. The Evangelicals held firmly to the traditional Calvinism of the Westminster Confession, sometimes in an intellectual dryasdust fashion and sometimes in a warmer evangelical fashion.

During the predominance of Moderatism in the later 18th century the Secession and Relief churches continued to flourish owing to the increase of population, the continued operation of patronage, the desire for a warmer fellowship and more stirring preaching than was often to be found in the parish church, and the rise of an independent middle class, which found more scope in the nonestablished churches.

The Evangelical Revival.—Despite the draining away of evangelical fervour into the Secession and Relief churches, the Evangelical party in the Church of Scotland was ready to take advantage of the change of atmosphere brought about by the French Revolution. There was a revulsion from the cult of reason toward the traditional, the romantic, and the mystical, and in some circles

the revolutionary idea of the rights of man produced a democratic, even secularist, ferment. It began to be suggested that one of the rights of man was to choose his religion and pay for it, the state neither establishing nor endowing any church.

By the turn of the century the evangelical revival in the Church of Scotland was making progress, aided indirectly by the movement led by the brothers Robert and James Haldane who afterward left the Church of Scotland. Leaders of talent and rank such as John Erskine (d. 1803), friend of George Whitefield, and Sir Henry Moncrieff Wellwood (1750–1827) worked for the evangelical revival, and then Andrew Thomson with his magazine the *Edinburgh Christian Instructor* began to build up a party of younger men who after his death in 1831 looked to Thomas Chalmers (*q.v.*) as their leader.

The Disruption and After.—Once again patronage became an issue, but only as part of a larger program. The Evangelical party, which dominated the General Assembly from 1834 onward, realized that Scotland had changed in two generations. Population had increased and was more than before concentrated in the larger cities and towns, where more parishes, churches, and schools were needed. Chalmers and his followers were distrustful of the democratic trends in the agitation for the Reform Bill of 1832 and did not favour popular election of ministers; yet they could only hope to hold the people by some relaxation of the patronage laws which would give the congregation a control of the choice of its minister. To effect this the General Assembly passed the Veto Act, in terms of which if a majority of the male heads of families in a parish disapproved of the patron's presentee, this should be sufficient reason for the presbytery to reject him.

The act was conservative in intention; but when it was challenged the law courts declared it *ultra vires* and the patrons' rights were upheld. To the Evangelicals this intervention of the law was an invasion of the church's spiritual jurisdiction over the settlement of pastors, and thus the question of patronage merged in the deeper question of spiritual independence. Again and again cases came before the courts, and whereas the assembly maintained its Veto Act the courts instructed presbyteries to disregard it.

More than one political leader in Scotland framed measures designed to provide a way out of the impasse, but the government in London was indifferent, and though in 1842 the General Assembly by a two to one majority adopted the Claim of Right setting forth the church's complaints about the encroachments of the civil courts, nothing was done. The majority of the Evangelical party then began to prepare to end their relationship with the state. This took place in May 1843, when over a third of the ministers, followed by about the same proportion of the laity, "went out" to form the Free Church of Scotland (*see* SCOTLAND, FREE CHURCH OF).

The Disruption, as this event was called, was a severe blow to the Church of Scotland. It still held the loyalty of many persons of all ranks, however, and soon new leaders arose to vitalize its parochial system and guide it into fresh service. Nevertheless the Disruption, by reducing the size and prestige of the established church, accelerated changes which were already in the offing In 1845 the state took over the management of the poor law previously vested in kirk sessions, and in 1872 the act for compulsory state education brought the church's control of the parochial schools to an end.

The later 19th century was a period of change. Innovations by Robert Lee (1804–68), designed to make worship more ordered and dignified, aroused controversy but gradually won acceptance. The growth of congregational organizations was largely due to the vision and perseverance of Archibald Hamilton Charteris (1835–1908), who was particularly active in the organization of women's work. A new emphasis on youth made the Sunday school an essential congregational agency and led to the founding of uniformed organizations of which the first was the Boys' Brigade. The Scoto-Catholic movement, as it is sometimes called, for improvements in worship, distinct from but related to that of Robert Lee, aimed successfully at beauty and symbolism in church furnishing, observance of the Christian year, especially Christmas and Holy Week, more frequent communion, and a willingness to contemplate closer relations with episcopal churches.

Reunion.—Patronage was abolished by act of Parliament in 1874, and though the bitterness engendered by a subsequent disestablishment campaign remained a barrier between the Church of Scotland and the United Free Church (*see* UNITED FREE CHURCH OF SCOTLAND), the atmosphere was so changed that in 1909 the two churches entered into "unrestricted conference." The prime demand of the United Free Church was freedom from state control, and that was found to be compatible with the national recognition of religion which was what the Church of Scotland chiefly valued in its relation to the state. The outcome was the framing of Articles Declaratory of the Constitution of the Church of Scotland in Matters Spiritual, their presentation to Parliament in the form of a bill which was passed in 1921, followed by the act of 1925 which dealt finally with the endowments of the Church of Scotland, and then, on that basis, by the union of the two churches in 1929 which achieved a Church of Scotland united, national, and free. A minority, however, stood out and continued under the name United Free Church.

The Mid-20th Century.—More notable than this union as a testimony to the vitality of the Church of Scotland is the way in which it adapted itself to changing conditions. Church extension had been going on in Scotland for two centuries, but in the 20th century the parochial system was challenged in a more insistent way by slum clearance, the growth of new suburbs and even of new towns, as vast numbers of the population were rapidly rehoused. The implications of this were realized by John White (1867–1951), minister of the Barony of Glasgow, whose persistent efforts over 20 years to meet the situation made the church as a whole conscious of its significance so that from 1950 to 1960 new churches were opened at the rate of one every month. Parallel to this extension went a readjustment of agencies which sometimes involved the closing of redundant churches. During the 30 years that followed the union of the United Free Church with the Church of Scotland nearly a quarter of the parishes or charges were merged or linked with other parishes in the 60 presbyteries.

The legislation associated with the union of 1929 threw increasing financial responsibility on congregations, particularly in the country parishes; and, despite the decline of rural life in general, they responded well to the challenge, though the average liberality of the total membership is still low.

The General Assembly's Foreign Mission Committee was formed in 1825 and Alexander Duff went to Calcutta in 1829 as the first official missionary of the church. By the second half of the 20th century the Overseas Council, comprising the Foreign Mission Committee, the Colonial and Continental Committee, the Church and Israel Committee, and the Committee on Inter-Church Aid and Refugee Service, was sending missionaries, chaplains, and other workers to share in the life and witness of indigenous churches in many lands.

The Church of Scotland, however, is in a missionary situation in Scotland itself. Although nearly half the children born in the country are baptized in infancy in the Church of Scotland, only a quarter of the total population (or over a third of those aged more than 20) are communicant members, while regular attenders at worship are estimated at about 7% of the total population. For many years there has been a decline in the number of children attending Sunday school and Bible classes.

The older methods of evangelism have continued in operation but there have also been experiments tending away from the large meeting toward intensive work among people in their homes and places of work. Parish missions and area missions, prepared by preliminary surveys and training of workers, have become common, and there have been approaches to special groups through school chaplains, industrial chaplains, and the Scottish Christian Industrial Order. The Iona community, founded by George MacLeod in 1938 and integrated into the organization of the church in 1951 (*see* IONA), has strongly influenced methods of evangelism as well as worship and the witness of the Christian in society. Another movement more widely spread is "Tell Scotland," begun as a radio mission, which sponsors visitation missions, house

churches. Bible study groups, as well as more spectacular efforts such as the "Kirk Weeks," held in imitation of the German *Kirchentag*.

The "Tell Scotland" movement and many other practical initiatives are ecumenical in the sense of being backed by other Protestant denominations in Scotland, but the latter are comparatively so small in membership that the Church of Scotland as a whole is little affected by them and does not feel the need of ecumenical support at the parochial level. Nevertheless the Church of Scotland is a member of the World Alliance of Reformed Churches (World Presbyterian Alliance), of the British Council of Churches, and of the World Council of Churches and has contributed to the leadership of these bodies. From 1932 conversations with the Church of England (in conjunction since 1954 with the Episcopal Church in Scotland) took place at intervals, but no important moves toward union or intercommunion were accepted.

The new stress on evangelism kindled interest in adult Christian education and the task of the laity in church and community. Not only did the number of elders increase by about a quarter after 1929, but there was a renewed sense of the spiritual potentialities of the eldership. The admission of women as elders has been proposed, but indifference and opposition, not least on the part of many women, have prevented it. Women, however, are often more active in their membership and more alive to the mission of the church than men are, largely because of the Woman's Guild, which is well organized and well led at every level and has a branch in almost every parish. Most of the deaconesses in the Church of Scotland are engaged in parochial work. Women are not eligible for the ministry, but deaconesses when suitably trained may be presented to presbyteries for license as preachers of the Word.

The interest of the church in the poor and handicapped has continued throughout the centuries in changing forms; but in the 20th century its machinery for giving effect to that interest has been greatly increased. The Committee on Social Service has under its charge many agencies, including homes for children of different ages, hostels for young men and for young women, eventide homes, as well as providing for special groups such as unmarried mothers.

The position of the church today presents peculiar, even paradoxical, features. Although it represents so large a part of Scottish Protestantism, its proportion of the total population is but moderate, and, if the test be devoted and effective membership, its position is weak. Having lost its statutory connection with education and the poor it is no longer at the centre of social life and can be ignored, as it is by many. On the other hand it is clearly the national church. The lord high commissioner, representing the sovereign, is an honoured guest at its annual General Assembly, the annual report of the assembly's Church and Nation Committee touches all aspects of the nation's life, and British governments sometimes pay attention to the General Assembly's utterances. Even Scotsmen who show no interest in the church's worship and teaching are concerned about it as an institution. When through Anglican-Presbyterian conversations its government seemed to be in question, strong general interest was aroused. In that sense the people feel the church belongs to them; it is a part of Scottish history, the product of a distinct national character as well as part of the Holy Catholic Church.

SCOTLAND, EPISCOPAL CHURCH IN, an independent province, of Scottish origin, within the Anglican Communion. Ecclesiastical history in Scotland during the first century after the Reformation is confused, with alternating periods of episcopalian and presbyterian supremacy (*see* PRESBYTERIANISM: *History of the Presbyterian Churches: Scotland*). After the Restoration in 1660 the two coalesced into a modified episcopacy, which might have united church and nation had not the two parties fallen apart after the accession of William and Mary, when Episcopalians were in conscience unable to take the oath of allegiance to them. Thus Presbyterianism was established as the national religion (1689). The Episcopal Church is the direct descendant of those churches that remained loyal to the episcopal tradition, and its bishops are the direct successors of those consecrated to Scottish sees after the Restoration.

Loyalty to the exiled Stuarts resulted in the implication of the Episcopal Church in the Jacobite risings of 1715 and 1745, after which penal laws reduced it almost to extinction. (*See* SCOTLAND: *History*.) The repeal of these laws in 1792 consequent on the death of Prince Charles Edward in 1788 marked a turning point, and the church began to revive. It was organized in seven dioceses; canons were enacted; churches and mission halls were built; schools were founded—signs of an astonishing recovery. An outstanding factor in this development is the increasing part taken by the laity in the affairs of the church, not only in financial matters through the Representative Church Council but also in matters liturgical and canonical by their membership of the Provincial Synod, the supreme legislative body, as authorized in 1961. The Provincial Synod is presided over by the primus, elected by the seven bishops from their number. The seven sees are: Aberdeen and Orkney; Argyll and the Isles; Brechin; Edinburgh; Glasgow and Galloway; Moray, Ross and Caithness; St. Andrews, Dunkeld and Dunblane. Communicants number about 56,000, clergy about 370.

The Scottish Communion Office, based on the liturgy in the service book imposed on Scotland by Charles I in 1637, took shape in 1764. In the 1920s the revision of the whole Prayer Book was undertaken and a complete Scottish Prayer Book was produced in 1929. For the most part this is an improved and amplified version of the Prayer Book of 1662, save for the liturgy which itself was revised slightly (*see* COMMON PRAYER, BOOK OF).

The Episcopal Church has undertaken missionary responsibilities overseas. It provided the endowment when the diocese of St.

John's in South Africa was founded in 1871; ever since, it has made substantial contributions annually to the work of the diocese, and a number of priests have gone out from Scotland to work there. Shortly after, responsibility was also accepted for the district of Chanda in India. A number of other missionary agencies are supported on a smaller scale. After World War I the new Social Service Board undertook moral welfare work, work among fisher folk, youth work, and the provision of "eventide" homes. The theological college is in Edinburgh.

See F. Goldie, ***A Short History of the Episcopal Church in Scotland*** (1951 [1952]). (T. Ha.)

SCOTLAND, FREE CHURCH OF, came into existence fully fledged on May 18, 1843, when 203 members of the General Assembly of the Church of Scotland marched out of St. Andrew's Church, having read and laid on the table a protest asserting that it was impossible for them, in view of the "recent encroachments of the civil courts, and the still more recent sanction of these decisions by the legislature," to hold a free assembly of the church. They therefore protested

> that it shall be lawful for us, and such other commissioners as may concur with us, to withdraw to a separate place of meeting, for the purpose of taking steps, for ourselves and all who adhere to us—maintaining with us the Confession of Faith and standards of the Church of Scotland as heretofore understood—for separating in an orderly way from the Establishment, and thereupon adopting such measures as may be competent to us, in humble dependence on God's grace and the aid of His Holy Spirit, for the advancement of His glory, and the extension of the gospel of our Lord and Saviour, and the administration of the affairs of Christ's house, according to His Holy Word.

In orderly procession they marched to Tanfield Hall over half a mile away, where they and delegates from all sympathizing congregations constituted themselves into the first General Assembly of the Church of Scotland, free. Thomas Chalmers (*q.v.*) was elected moderator by acclamation. Of the vast amount of business transacted in a crowded fortnight the outstanding item was the Act of Separation and Deed of Demission on Tuesday, May 23, 1843, to which 396 ministers and professors publicly appended their names (others being added later, bringing the total to 474) by which they renounced all claim to the benefices they had held in connection with the establishment, declaring them to be vacant, and consenting to their being dealt with as such, thus voluntarily surrendering churches, professorships, manses, and glebes and an income from the state calculated at over £100,000 per annum. This was the real act of disruption—a disruption not from their brethren in the ministry but from the state. It would, to their mind, have been a still more "glorious" disruption had all the ministers of the Church of Scotland swelled their ranks in Tanfield Hall. Though the General Assembly of 1842 had passed the Claim, Declaration and Protest, popularly known as the Claim of Right, by a majority of over two to one, it was only a minority of four to seven of the ministers that followed Chalmers to this, its logical conclusion; the proportion among both office-bearers and ordinary members was distinctly higher.

Ten Years' Conflict Before the Disruption.—Though the tangled story of the years 1833–43 belongs chronologically to the article Scotland, Church of, it is necessary to recall the salient points which brought the Church of Scotland to such an impasse. The root of all the bitterness was the reimposition of the law of patronage in 1712. What the Evangelicals were fighting for were the rights of the Christian people in the calling of their minister and the right of the church to initiate new work to areas of increasing population. A remedy was found in two assembly acts of 1834, the Veto Act and the Chapel Act. For some years the remedy seemed effective. The great bulk of the church rejoiced in their smooth operation. However, some patrons began to feel that both acts impinged on their privileges. An appeal to the law courts by one patron and his vetoed presentee proved successful. This encouraged other patrons to present cases not dissimilar, but making progressive inroads on the powers hitherto claimed and exercised by the courts of the church.

Both church and law courts hardened their positions in the ten years 1833–43. The General Assembly, which was at first content to accept patronage while tempering its operation, demanded in 1842 its abolition as the only way out. The Court of Session, while at the outset recognizing a coordinate jurisdiction of the church in spiritual things, came to deny that jurisdiction in all cases in which it had not been conferred by definite statute. Some of the judicial dicta help to explain the passionate earnestness of the final paragraph of the Claim of Right, which thus begins:

> And, finally, the General Assembly call the Christian people of this kingdom, and all the churches of the Reformation throughout the world, who hold the great doctrine of the sole headship of the Lord Jesus Christ over His church, to witness, that it is for adherence to that doctrine, as set forth in their Confession of Faith, and ratified by the laws of this kingdom, and for the maintenance by them of the jurisdiction of the office-bearers, and the freedom and privileges of the members of the Church from that doctrine following, that this Church is subjected to hardship, and that the rights so sacredly pledged and secured to her are put in peril.

When the final appeal to Parliament failed, the church had to prepare for an uncertain future; for months, committees had been busy preparing plans, gathering money from willing givers, for every branch of work to which it had been committed in its undivided state.

Early Days.—The basis of the support of the Free Church was the Sustentation Fund, the principles and details of which had been elaborated by Thomas Chalmers himself—a central fund for the maintenance of ordinances, from which every minister in a charge would receive an equal dividend. In the very first year the 583 ministers received at the rate of £105. Throughout the whole course of its history this fund grew with the growing church. But the stupendous financial burden facing its first assembly arose from the grim facts of the situation. There were no churches for their services of worship, no houses for their ministers to live in, no places for the training of the ministry, few schools for their children to be educated in, no mission premises abroad, for though every overseas missionary save one had intimated his adherence to them they had to do so at the expense of buildings and equipment. Special building funds for churches, for manses, for a college, for schools and schoolhouses, and for foreign mission stations were launched and entrusted to various leaders. Everything had to be done on the simplest scale, but before Chalmers died, in 1847, he could see every activity of the church adequately housed or in process of being so. It was an unprecedented exhibition of Christian liberality, for the great bulk of the funds came from loyal members, though occasional donations from outside sympathizers helped to swell the total.

After the first difficulties had been overcome, the church embarked on a career of orderly, if less sensational, progress. It made the minimum of changes in constitution and general setup, being eager to prove that the former constitution, if rightly understood and fully operated, was adequate for the religious needs of the land. The reintroduction of deacons ensured the progress of the Sustentation Fund. The addition of the Claim of Right of 1842 and the Protest of 1843 to the subordinate standards of the church ensured that the claim to spiritual independence should not be ignored or minimized. The church was fortunate in securing a succession of strong leaders both at home and abroad. In domestic affairs the outstanding leaders of its earliest days, Chalmers, R. S. Candlish, and William Cunningham, were succeeded by Robert Rainy, who, for nearly two generations, was its trusted guide and pilot and who left two younger ministers, Archibald Henderson and Alexander Martin, to carry on his tradition into the United Free Church. It produced notable preachers, teachers, and evangelists at home, and in the foreign field it led in educational work. Alexander Duff in Calcutta, John Wilson in Bombay, William Miller in Madras, and Stephen Hislop in Nagpur inaugurated and developed Christian colleges which, though criticized by some as placing education before evangelism, did much to develop an India permeated with Christian values. For Africa, the institutions at Livingstonia and Lovedale under Robert Laws and James Stewart did a similar service.

The emergence of the Free Church stirred hopes of union among those already outside the Church of Scotland. So 1852 saw the accession of one smaller body, the Original Secession Church

(Associate Synod of Original Seceders), and 1863 saw the beginning of wider negotiations with the two larger denominations in Scotland, the United Presbyterian Church (*q.v.*) and the Reformed Presbyterian Church (*see* CAMERONIANS). With the latter they were successful and a union took place in 1876; with the former they failed after ten years of patient and hopeful negotiation through the stubbornness of a minority within the Free Church which threatened legal action if they were forced to unite with a professedly Voluntary church (*i.e.*, one which opposed the establishment principle and held that the church should be maintained only by voluntary support of its members). The two results of the ten years were a Mutual Eligibility Act of 1874, by which a minister of either church might be called to a congregation in the other, and a great mass of documents which materially shortened the later successful negotiations initiated in 1896.

Theological Developments.—The mind of the Free Church was not absorbed only in questions of ecclesiastical polity. The colleges of the church were the home of the most active interest in theological and historical questions. There was a stormy period, however, when extreme conservatism appeared to gain a victory. In 1870 W. Robertson Smith (*q.v.*) was ordained to the office of professor of Oriental languages and Old Testament exegesis in the Free Church College, Aberdeen. There from the first he advocated views which though now widely accepted were then regarded with apprehension. In 1876 a committee of the Free Church reported so adversely on his writings that Smith demanded a formal trial. The indictment failed; but a vote of want of confidence was passed, and in 1881 he was removed from his chair. This event, however, was no adequate expression of the real mind of the church. During the last quarter of the 19th century the Free Church continued to be the most active, theologically, of the Scottish churches.

The college chairs were almost uniformly filled by theologians and historians of progressive views, inspired more or less by A. B. Davidson of New College, Edinburgh. A. B. Bruce was appointed to the chair of apologetics and New Testament exegesis in the Glasgow College in 1875; Henry Drummond was made lecturer in natural science in the same college in 1877 and became professor in 1884; and George Adam Smith was called to the Hebrew chair in 1892.

Attempts were made between the years 1890 and 1895 to bring all these professors except Davidson (similar attacks were also made on Marcus Dods, afterward principal of the New College, Edinburgh) to the bar of the assembly for unsound teaching or writing; but in every case these were abortive, the assembly never taking any step beyond warning the accused that their primary duty was to teach and defend the church's faith as embodied in the confession. In 1892 the Free Church, following the example of the United Presbyterian Church (1879), passed a Declaratory Act relaxing the stringency of subscription to the confession, with the result that a small number of ministers and congregations, mostly in the Highlands, severed their connection with the church and formed the Free Presbyterian Church of Scotland, on strictly orthodox lines.

Meanwhile other changes were taking place. The standard of parochial and congregational activity was raised, the use of instrumental music was sanctioned, and special attention given to the promotion of edification, order, and reverence in public worship. And the establishment principle was almost entirely abandoned.

Incorporation in United Free Church.—During the last four or five years of the 19th century the Free and United Presbyterian churches devoted their energy to the arrangement of an incorporating union. The synod of the United Presbyterian Church resolved in 1896 to "take steps toward union," and next year the Free Church assembly responded by appointing a committee to confer with a committee of the other church. The joint committee discovered a "remarkable and happy agreement" between the doctrinal standards, rules, and methods of the two bodies, and with very few concessions on either side a common constitution and common "questions and formula" for the admission of ministers and office-bearers were arranged. A minority, always dwindling, of the Free Church assembly protested against the proposed union and threatened if it were carried through to test its legality in the courts; nevertheless the union was carried through. The supreme courts of the churches met separately for the last time on Oct. 30, 1900, and on the following day the union was completed, and the United Free Church of Scotland (*q.v.*) entered on its career.

The Free Church Minority ("Wee Frees").—The protesting and dissenting minority at once claimed to be the Free Church. Denied admission to the assembly hall, they adjourned to another building, where they held, so they claimed, the remaining sittings of the assembly. At their next assembly (1901) it was stated that there had adhered to their antiunionist program 25 ministers and at least 63 congregations. The character of the church is indicated by the fact that its office-bearers were the survivors of the minorities of the church who had protested against the disestablishment resolution, against the toleration of any tinge of higher criticism in the theological chairs, and against the use in public worship of organs or of "human hymns." The congregations were mainly in the Gaelic-speaking districts of the Highlands and islands. Many held high hopes of considerable accessions if they won the lawsuit which they had entered into (*Bannatyne* v. *Overton*) claiming that they were the rightful owners of the properties which had belonged to the Free Church and had been carried into the United Free Church. But there was little change of allegiance when the House of Lords (1904) gave decision in their favour. Nevertheless the church continued to hold its own in the areas of its original congregations.

In the mid-1960s its General Assembly comprised 15 presbyteries, of which 12 were in Northern Scotland and the islands. It had foreign mission stations in South Africa, Peru, and India. Under its overseas missions it had six congregations in Canada and the United States. For the training of its ministers it maintained a strong theological college in Edinburgh. *See* also PRESBYTERIANISM; SCOTLAND, CHURCH OF; UNITED FREE CHURCH OF SCOTLAND.

SCOTLAND YARD, the headquarters of the metropolitan police of London, Eng., was originally an area just off Whitehall, and took its name from the palace, dating back to the reign of Edgar (959–975), which stood on the site. Edgar gave King Kenneth of Scotland a piece of ground lying beside the new palace of Westminster for his residence, requiring him to make a yearly visit to London to pay homage for the kingdom of Scotland. The palace built there by Kenneth remained the property of the Scottish kings, where they stayed when visiting London, but in the reign of Henry II, after the rebellion of William of Scotland in 1173–74, it was "resumed into the king of England's hands." Margaret, the widow of James IV of Scotland and sister of Henry VIII of England, appears to have been the last Scottish sovereign to have made use of the palace, living there for a considerable time after the death of her husband in 1513, but by the time Elizabeth I came to the throne it was a neglected ruin.

By James I's reign the site, which had come to be known as "Scotland," was divided into two yards, known as Great Scotland Yard and Middle Scotland Yard, and was used for government buildings. These included the official residence of the surveyor of works to the crown, which was at one time occupied by Inigo Jones and his successors Sir John Denham and Sir Christopher Wren, who had offices there and designed a house in Scotland Yard for Sir John Vanbrugh. This house was built from the ruins of buildings in Whitehall destroyed by fire in 1697. John Milton, when appointed secretary for foreign tongues under Oliver Cromwell's Commonwealth in 1649, soon found it convenient to take up official residence at Scotland Yard, where he lived until he moved to Petty France in 1651. Other notable inhabitants of Scotland Yard include Susannah Cibber, wife of the actor and playwright Theophilus Cibber and the sister of Thomas Arne, the composer; and Thomas Campbell, the Scottish poet.

Early Police Connections.—The first association of police with Scotland Yard appears to have been in 1662, when the first police or improvement commissioners for London and Westminster set up offices there, but these commissioners were more concerned with paving, lighting, and cleaning of streets than with police duties as they are understood today. A further association occurred when Col. Sir Thomas de Veil, the first of the Bow Street Magistrates, had an office in Scotland Yard, where he acted as an agent for memorials to public departments before moving to Bow Street about 1735. But the direct association between Scotland Yard and the metropolitan police started when the force was formed in 1829 by Sir Robert Peel, the home secretary of the time. The newly formed force was to police the area in and immediately around London—with the exception of the City of London, with its area of just more than one square mile, which was not included but which was to form its own police force ten years later—and the headquarters of the metropolitan force were at no. 4, Whitehall Place, with a police station at the rear, entered from Scotland Yard itself. Although the proper official address of the headquarters was no. 4, Whitehall Place, from the very beginning it was always referred to as Scotland Yard by the press and others.

At the time of their formation, the metropolitan police were placed under the leadership of two joint commissioners, Richard Mayne (made K.C.B. in 1851) and Col. Charles Rowan (made K.C.B. in 1848), the former "a sensible lawyer" and the latter "a military man conversant with the details of the police system in Ireland." At first the new force met with fierce and bitter opposition from many quarters and was referred to by many uncomplimentary names, including the "raw lobster gang," "Peel's bloody gang," and "the blue devils," but under the wise and able control of Mayne and Rowan they succeeded in overcoming this opposition and by the time of Mayne's death in 1868 (Rowan had retired in 1850) the force had gone far to establish the reputation and popularity which it enjoyed thereafter.

Building Development.—As the work and duties of Scotland Yard increased, adjoining premises were taken over and by the early 1880s the headquarters consisted of a number of separate buildings which, apart from the inconvenience, were extremely overcrowded. Important records and papers were crammed into cupboards and piled high on landings, and the provision of a new headquarters had become a pressing necessity. It was generally agreed that the headquarters should be situated in the immediate vicinity of the home office and the seat of government, since the home secretary is directly responsible to parliament for police matters. The only acceptable site was one on reclaimed land made available by the construction of the Thames Embankment, which was opened in 1870. On this site of about 70,000 sq.ft., Colonel Mapelson had begun to build a national opera house on a very ambitious scale. The foundation stone was laid in 1875 by the duke of Edinburgh and the intended opera house had been partly constructed, between £80,000 and £90,000 having been spent on it, when the scheme fell through for lack of further financial support.

A private offer was made in 1880 to the deputy surveyor of the police to buy the site as it stood for £25,000, and after very lengthy discussion the site was finally purchased in 1886. Richard Norman Shaw was entrusted with the designing of the building and his plan, although adopted, was the subject of a great deal of disagreement in official and other circles. By late 1890 the building was completed, faced up to the top of the second floor with 2,500 tons of granite quarried and dressed by the convicts of Dartmoor, and continuing upward in red brick with Portland stone dressings. On May 11, 1941, a high explosive bomb fell on one corner, causing extensive damage and resulting in many tons of masonry and millions of index cards from the registry two floors above falling into the commissioner's room. No lives were lost, but had the building been less substantial far greater damage would have been done.

The move of all the headquarters staff to the new premises took place in Dec. 1890, and the building was officially designated New Scotland Yard. Scotland House (to become known later as New Scotland Yard South), occupied by the receiver for the metropolitan police district, to the south of New Scotland Yard and connected by an archway over the road, was added several years later, from Shaw's designs. At the same time were added the wrought-iron entrance gates, which had been designed by Thomas Elsley as an exhibition piece and found by Shaw at Elsley's shop, standing unused.

By 1935 the position at New Scotland Yard had once again reached a point where some extension or re-siting was very necessary, and it was decided by the commissioners of the office of works to incorporate a new police building in the development scheme for Richmond Terrace, Westminster, and a site extending northward from New Scotland Yard was agreed upon.

The reproduction of Shaw's design in the new building was found unacceptable on the grounds that it would be difficult to reconcile it with further developments in the immediate vicinity and that New Scotland Yard itself was considered to be wasteful in planning by modern standards. A building more in relationship with modern ideas was required, and indeed it was even suggested that Shaw's building should be demolished and replaced by buildings with better accommodations and which were more in harmony with a general development scheme. This suggestion was, however, dropped when questions of finance and the remoteness of such a general scheme were raised.

W. Curtis Green was the man selected to design the new extension, which soon began to take shape. At the outbreak of World War II in September 1939, however, the building was still 14 months from completion. Under increased pressure of war duties, it was found necessary to move some personnel into the unfinished building, and in early 1940 parts of it were occupied while work was still in progress on the upper part of the structure. By December 1940 the building was ready for complete occupation, but certain parts of it were, as a wartime necessity, used for purposes other than police functions.

The section of the fighting services known as combined operations took up its headquarters in the building in 1940, and occupied part of it until 1945. It was not until the latter year that the building became completely available for its original purpose. By mid-century it housed the immense telephone switchboard of Scotland Yard, the information room with its emergency 999 service, the forensic science laboratory, the criminal record office, the fingerprint and photography departments, and other branches of the criminal investigation department. At first it was decided to name the new building Richmond House, as the first step in the Richmond Terrace Development Scheme, but on reconsideration it was thought that the title of Scotland Yard had come to have such a special meaning for the metropolitan police that its use should be retained.

The new building was accordingly designated New Scotland Yard North, and the official name of Shaw's building was altered to New Scotland Yard Central. Scotland House, the receiver for the metropolitan police district, became officially New Scotland Yard South. By the 1960s, New Scotland Yard Central was inadequate, and it was planned to re-site by 1967 the whole metropolitan police headquarters at the east end of Victoria St., near the Houses of Parliament.

Apart from the 175 police stations and other police buildings in the metropolitan police district, there are the public carriage office, the police garage and lost property office at Lambeth, the aliens' registration office in Theobalds Road, and offices at Walton Street, Kensington, and Ramillies Place, Westminster. All are working branches of Scotland Yard's headquarters.

Organization.—At its commencement in 1829, the extent of the metropolitan police district controlled from Scotland Yard was approximately 120 sq.mi., with an estimated population of less than 1,500,000 persons; for this area there was a police force of 1,000. Ten years later, in 1839, the area was extended to 699.42 sq.mi., and the strength of the police had been increased to 3,350 for a population of nearly 2,250,000. No further alteration was made to the size of the district until 1947, when, by a readjustment of police boundaries under the Police Act of 1946, it was extended to cover 734.88 sq.mi. By the early 1960s the strength of the

force had increased to over 18,000, for a population exceeding 8,000,000. The London Government Act, 1963, increased the metropolitan police district by about 51 sq.mi., to a total of 786 sq.mi.

At the top of the administration of Scotland Yard and in charge of all the police of the metropolis is the commissioner, who is appointed by the crown on the recommendation of the home secretary. Directly under the commissioner is the deputy commissioner, and below them at headquarters there are six main departments: administration ("A"); traffic ("B"); criminal investigation ("C"); organization ("D"); secretariat ("S"); and the legal department ("L"). The first four of these departments are each headed by an assistant commissioner. Each assistant likewise is appointed by the crown on the recommendation of the home secretary. The commissioner, deputy commissioner, and assistant commissioners are also justices of the peace for Greater London and the counties of Surrey, Hertfordshire, Essex, Berkshire, Kent, and Buckinghamshire, but their functions as justices are limited to executive police matters.

The assistant commissioner at the head of the administration department is responsible for discipline, distribution, and other administrative matters in the force, and his department includes the women police and mounted branch. Not the least of his duties is the control of all police arrangements in connection with the many ceremonies in London.

The traffic department deals with all traffic matters, including supervision of the public carriage office (with its licensing and control of cabs and their drivers, and the drivers and conductors of buses, coaches, and trolley vehicles in the metropolitan area), police transport, the police motor driving school, and the lost property office.

The criminal investigation department deals with all aspects of criminal investigation, including the criminal record office, fingerprint and photography sections, the company fraud squad, the flying squad, special branch, the metropolitan police laboratory, and the detective training school.

The organization department is concerned with civil defense, supplies and equipment, first aid, buildings and housing, recruitment and training, police dogs, medical services, communications including the information room, and welfare.

The secretarial department is under the control of the secretary, who is not a police officer but head of the civilian staff of the metropolitan police force, appointed by the home secretary on the recommendation of the commissioner. His department employs more than 4,000 civilians in all its secretarial work, including its vast registry, pay and pensions, and the press and information department.

The legal department is headed by a solicitor. The solicitor to the metropolitan police district is appointed by the home secretary on the recommendation of the commissioner and is also the prosecuting solicitor to the quarter sessions within the metropolitan area.

In addition to these main departments, a small research and planning branch was established, responsible directly to the commissioner, through the deputy commissioner, for keeping the whole organization under constant review, particularly with regard to manpower and future planning. (R. M. H.; X.)

SCOTS LAW. At the union of the Parliaments of England and Scotland in 1707, the legal systems of the two countries were very dissimilar. Scotland, mainly in the preceding century, had adopted as a guide much of the Roman law, as developed by the jurists of Holland and France. But it is a fallacy to suppose that the law of Scotland is founded on the law of Rome: the Scots only turned to Roman law when there was a gap in their own common or customary law. There is, however, a considerable infusion of Roman law, not least in the field of nomenclature and in the emphasis on principle rather than precedent. English lawyers, on the other hand, had forgotten or refused to acknowledge the debt owed to Rome by both common law and equity. At the union the law of Scotland had been set forth in the *Institutions* (1681) of Lord Stair, a masterpiece of lucidity and orderly arrangement. In England there was little guidance through a maze of precedents and forms of pleading beyond the difficult pages of Coke. Perhaps the most important distinction was the fact that Scotland, unlike England, did not separate the administration of equity and law.

The Scottish conception of equity is not, like the English, that of a system running parallel to the common law (*see* EQUITY). It is rather: (1) a few fairly simple rules aimed at supplementing the law in order in avoid hardship; and (2) the relegation of certain remedies to the class of equitable remedies, which the court has a large discretion to grant or withhold. The word "equity" in the law of Scotland has always retained its original meaning. The Scottish outlook upon this whole topic places Scots law clearly alongside the continental and not the English system.

Historical Development.—The period following the union has been characterized by the assimilation of Scots and English law. One main cause of assimilation is that much of the existing law of Scotland depends on statutes applicable to both countries. The House of Lords, consisting in its legal aspect until 1876 exclusively of English lawyers acting as the supreme court of appeal from Scotland, had a tendency to apply English law in Scottish appeals, and in some cases seems to have forgotten the distinction between its legislative and its judicial functions. Another cause of assimilation is the influence of text writers, some of whom, such as G. J. Bell, have tended to treat English law as though it were the law of their own country. The citation, too, of English authorities in court (partly explicable by the dearth of modern Scottish textbooks), despite judicial remonstrance, has had considerable effect. Not surprisingly the greatest assimilation has been in the field of mercantile law. In other fields the systems are still widely separated.

Courts of Law.—The system of Scottish courts is completely different from that of the English and here again is closer to the continental pattern. The supreme Scottish court (the House of Lords, which is not a native court, being for the moment disregarded) is the Court of Session, instituted by King James V in 1532 probably upon a French model. The court has two main functions. It has original jurisdiction in a very wide range of cases, which is exclusive in a few matters such as actions affecting status (*e.g.*, divorce and bastardy); in its appellate capacity it hears appeals (by reclaiming petition) from the nine Court of Session courts of first instance (called compendiously the Outer House), each presided over by a lord ordinary, and also from the sheriff's courts. The appellate court (Inner House) sits in two divisions, the first and second, presided over respectively by the lord president of the Court of Session (*see* LORD JUSTICE-GENERAL) and the lord justice clerk (*q.v.*). All the judges have the courtesy title of "lord," but are not on that account peers.

While the judges of the Court of Session are traditionally judges of both fact and law, in the early 19th century the civil jury was introduced, less because it was wanted in Scotland than because the House of Lords was weary of the great number of appeals which (since the decision of a jury is not in the ordinary sense appealable) would be drastically reduced by the change. From the Inner House appeal lies in many cases to the House of Lords as of right and not, as in England, by leave. The right of audience in the Court of Session is possessed exclusively by members of the faculty of advocates.

The lower civil courts are first the sheriff courts, which are ancient courts distributed by counties; then the burgh police courts and justice of the peace courts. Sheriff Courts are manned by (1) the sheriff principal and (2) the sheriff substitute. The former (with administrative as well as judicial functions) is in civil matters an appellate judge only and hears appeals from the sheriffs substitute of his jurisdiction. The sheriff substitute's absurd title conceals his great importance. For except in divorce and one or two other less important matters his jurisdiction almost exactly coincides with that of the Court of Session. As a local and comparatively inexpensive court the Sheriff Court is more popular than the Court of Session. It will be seen that the Sheriff Court (which has also a wide criminal jurisdiction) cannot for a moment be compared with the English County Court, with its very limited civil jurisdiction and complete lack of criminal jurisdiction. The Justice Court has a limited jurisdiction in small debt actions.

The dean of Guild Court has a quaestorial jurisdiction in questions of building in the towns.

It should be added that the Court of Session has absorbed the functions of certain ancient courts, the Court of Exchequer, the Admiralty Court, the Teind (or Tithe) Court, and the Commissary Court, which dealt with questions of marriage law and executry, while the judges have by statute been given separate duties in a Lands Valuation Appeal Court, a Registration Appeal Court, and an Election Petition Court.

The Scottish Land Court, established in 1911, has jurisdiction in a wide range of matters relating to agriculture. Questions between landlords and tenants of agricultural holdings may be brought before it by judicial process or, by agreement of parties, in lieu of arbitration. It also deals with questions referred by the secretary of state for Scotland.

Land Tenure.—The law of land tenure has been complicated by the survival of much of the feudal system. In theory the crown is the ultimate owner of land, which passes from it to others in the first place through a grant. The grantee or "vassal" may make a subaltern grant and so can successive grantees, by what is called subinfeudation, a process forbidden in England by the statute Quia Emptores (1290). The grantee can also sell his land so as to take himself out of the descending chain and put a purchaser in his place. As in other systems, land can be used to provide security for a loan to the owner of it. This is done by a bond with a disposition of the land in security, or by an outright conveyance together with a "back letter" from the lender entitling the owner to recover the land on repayment of the loan. The word mortgage is not a Scottish term. The consequence of unrestricted subinfeudation has been that the rights of subject superiors—the superior is the person who feus or grants the land—have bulked much more largely in Scotland than in England. A series of statutes, culminating in the Feudal Casualties Act, 1914, abolished all payments exigible from the vassal except feu duty, and at mid-20th century it might be said that a feu, the normal tenure in Scotland, was equivalent to an English freehold, subject, in cases where there was a feu duty, to a perpetual rent charge. There is, however, a very important distinction in the system of registration of title, only imperfectly developed in England. In Scotland, since the establishment of the Register of Sasines in 1617, all deeds relating to land may be recorded in that register, and it has long been established that a purchaser, or a lender on heritable security, is entitled to trust to the register, and is not affected by any conveyance or burden not there recorded.

The law of house leases differs markedly from the law of England in a number of ways. For example, Scots law demands in most cases that notice of intention to remove be given even if the lease itself provides for termination at a particular date. Failing this the lease will be continued by what is called tacit relocation. Also, the landlord is bound to provide and to maintain premises reasonably fit for the purposes of the let. Failure to repair may be met by retention of the rent by the tenant. On destruction of the premises both parties are freed from their obligations. Local rates in Scotland, formerly payable partly by the owner of property and partly by the occupier, are payable only by the occupier.

The law of agricultural leases is very different from the law of town leases and is complex. For example, a tenant is entitled to compensation for disturbance if given notice to quit, for improvements made by him, and for damage done by game. A tenant is entitled, on conditions, to bequeath his lease. Further specialties apply in the case of the so-called small landholder and crofter by virtue of various statutes. The Crofters Act, 1955, established a crofters' commission to promote the welfare of the crofting communities.

The Rent Restriction Acts, running from 1915 onward, are designed to prevent increase of the rents of small and medium houses and to give security of tenure. While no doubt serving these purposes, the acts led to a natural reluctance on the part of owners to spend money on what, with the diminished purchasing power of money, was an unprofitable investment. This in turn led to a serious deterioration in the condition of property covered by the acts. Consequently, in the 1950s, legislation considerably relaxed the control of rents and enabled owners to recover more readily the possession of their property (*see* LANDLORD AND TENANT).

Rights in Land.—Apart from its theoretical ownership of all Scottish land the crown is an important owner of heritable property; *i.e.*, land and what is built upon or planted in land. Its rights are known as the *regalia*. Some are *majora* and are inalienable. The *minora* or lesser rights may be alienated.

The foreshore of the sea may be alienated but not the public rights to anchor boats, embark, and disembark. Mention may be made of particular *regalia minora* such as the rights to salmon fishing, to precious metals, and to highways. Possession of heritage has some important consequences. Thus a bona fide possessor who unjustifiably takes the produce of the land need not make it good, in contradistinction to the possessor in bad faith, who must pay penal damages. Again a bona fide possessor is entitled to recompense for improvements.

The individual owner of land is entitled in theory to use it as he likes, but there are numerous statutory restrictions and disabilities. Among common-law rights, the right of support of land in its natural state by the land of one's neighbours is important. Surface or percolating water may be impounded but water in a stream may not be prevented from descending to lower proprietors. Where the lands of several proprietors adjoin a loch, they have a joint right in it. The right to fish in inland waters and the right to take game are incidents of property. It is open to a proprietor of land to confer upon neighbouring proprietors what is called a servitude; *i.e.*, the right to use the grantor's land in some way (a positive servitude) or the right to restrain the grantor from using his land in some way (a negative servitude). Examples would be, respectively, a right of way given to X over A's land and a right to X of preventing A from building above a certain height on his, A's, land. A public right of way, unlike a servitude, exists for the benefit of the public and not for the benefit of a particular piece of land. When land is held on a title *ex facie* valid for 20 years recorded in the register, an unchallengeable title is acquired by prescription.

Husband and Wife: Children.—The enfranchisement of women has placed husband and wife, as in England, upon an almost equal footing in matters of property. Gone are the days when on marriage the wife's whole movable property became her husband's and his assent was needed to any transaction affecting her heritage. In the law of marriage and divorce, too, the two systems have been gradually drawing closer. Thus the celebrated irregular marriage of Scotland has all but disappeared, though irregular marriage through "cohabitation with habit and repute" remains valid. "Gretna Green" is no more. Yet in fairness it should be realized that the irregular marriage was as binding as the regular and found a warranty in the canon law. Its abolition, many think, was a misfortune. In the law of divorce, on the other hand, English law has come closer to Scots law. In Scotland, divorce on the grounds of adultery and desertion was allowed to either party from shortly after the Reformation (1560). Today divorce is granted for adultery and for desertion by either spouse for three years; as also on the ground of cruelty, unnatural vice, and incurable insanity, as in England. One very important difference between the two systems is that in England "recriminations," *i.e.*, the answer by a respondent that the petitioner has also committed adultery, is a bar to a divorce unless the court exercises discretion. In Scotland recrimination is no defense and a party, though himself or herself guilty of adultery, is entitled to divorce when the other party has committed adultery. Cross divorce is the solution.

In Scotland a decree of divorce dissolves the marriage at once, a contrast with the English rule. In both countries the crown may interest itself in the proceedings as, for example, to discover collusion or, in England, concealment of adultery by the petitioner. In Scotland this intervention is made by the lord advocate. It is rare, probably because the law does not recognize recrimination. There is no queen's proctor. For the matrimonial offenses of adultery and cruelty (including habitual drunkenness) the

courts grant, if sought, the lesser remedy of judicial separation. This, if allowed, is normally accompanied by an award of aliment. No divorce or separation decree will be pronounced unless the court is satisfied that the best arrangements possible have been made for any children under 16 years of age. For property division on divorce, until 1964 the guilty spouse was treated as notionally dead and the legal rights exigible on death (see *Succession*, below) were similarly exigible on divorce. From 1964 the successful pursuer in the action of divorce might ask the court for an order for payment to him (or her) by the defender of a capital sum, or a periodical allowance, or both. Any order for a periodical payment is variable on change of circumstances, and terminates on remarriage or death of the pursuer.

Children.—Scots law divides minority into: (1) minority proper, from 12 to 21 for girls, 14 to 21 for boys; and (2) pupillarity, up to 12 and 14 respectively. Pupils act by their tutors, normally the father. Minors act with the consent of their curators, normally the father. A pupil can never act for himself but a minor, if he has no father, need have no curator and can legally treat himself as if he were major. The independence thus allowed to young people is an outstanding feature of the law. But 16 is the lowest age for marriage. Disadvantageous transactions by minors and pupils can be set aside within four years of attaining 21.

Intestate Succession.—Scots law never admitted absolute freedom of bequest where there was a surviving spouse or child. A distinction was drawn between heritable and movable property. A widow has a legal right in movable property (*jus relictae*); to one-half of her husband's movable property if there is no surviving child; to one-third, if there is. A widower since 1881 has a similar right in the movable property of his wife (*jus relicti*). Children have a legal right in the movable estate of each parent, one-half if there is no surviving spouse, one-third if there is. Legal rights cannot be excluded or limited by will, and attempted disregard of this may be successfully challenged in the courts.

In heritable property the widow had a legal right (terce) to a liferent (use and enjoyment for life) of one-third. A widower generally had a right of courtesy which gave him a liferent of the whole of the wife's estate. The ancient distinction between heritable and movable property, however, as well as the legal rights of terce and courtesy, were abolished by the Succession (Scotland) Act, 1964. Under this statute, if a husband or wife dies intestate the surviving spouse may claim the dwelling house (belonging to the deceased) or in certain cases its value up to £15,000; and furniture and plenishings up to the value of £5,000. If there is no issue the surviving spouse can also claim £5,000; and, if there is issue, £2,500. If the surviving spouse, however, is left a legacy he or she cannot take both this and the benefits under the act. If a woman dies intestate leaving illegitimate children those who survive take the whole of her estate.

Testate Succession.—No legacy made orally is valid unless it is of £100 Scots (£8 6*s.* 8*d.*) or less. This apart, a will must be made by a writing signed and witnessed as a deed (by two witnesses) or by a writing entirely in the testator's handwriting and signed by him. When a testator cannot write, the will may be signed for him by a solicitor, notary, justice, or parish minister.

The validity of a will is, in Scots law, not affected by the subsequent marriage of the testator. With considerable differences of detail, the law of wills is not markedly different from that of England. However, the existence in Scotland of "legal rights" to succeed introduces a distinctive complication. (*See* also WILL.)

Executors and Trustees.—These are persons nominated by the deceased (executors nominate) or appointed by the court (executors dative) who alone are entitled to administer the estate and pay creditors and legatees. Sanction to act is conferred by confirmation; the term probate is not used in Scotland. Any other person dealing with the estate is called a *vitious intromitter* and may, unless relieved by the court, incur liability for the debts of the deceased. A special summary process is competent in the case of small estates of a few hundred pounds in value. The heir of an executor does not succeed to his office. The same persons are frequently executors and trustees in estates of any size and especially where life interests have to be carried on. The law of trusts, contained principally in the Trusts (Scotland) Act, 1921, resembles the law in England in many respects, but the conception of holdings in trust as a sort of property running parallel to legal property is quite foreign.

A Scottish trust is normally constituted by an act of its creator, but it may also arise through implication from circumstances. Writing is not in all cases necessary. Trustees act by a majority. They may assume new trustees and may resign if they provide for the continuance of the trust. A trust may be terminated with the consent of grantor and beneficiaries, but a trust taking effect on its creator's death may not be terminated even with the beneficiaries' consent if its purpose is alimentary; *i.e.*, for the maintenance of the beneficiary. Such a protected trust may be created in favour of a man.

Contract.—There are three possible forms of contract: it must be writing (*e.g.*, for sale of land); it may be made orally but must be proved by writing (*e.g.*, contracts of an unusual nature); or it may be made and proved in any way (*e.g.*, sale of goods). The specialties of the document under seal are unknown, and consideration (something of value given in exchange) is unnecessary. Where writing is needed merely by way of proof and none is available, the party desiring to prove the contract may have the other put on oath and called upon to admit the contract. If this fails only part performance can save it. The only drawback to a contract lacking consideration is that it must be proved by writing. It is a peculiarity of Scots law that when a third party, X, is deliberately benefited by a contract between A and B, X has a right to sue A or B if either of them fails to perform the obligation. Where one party has been precluded through some cause beyond his control from performing his obligation, the law of Scotland enforces the return of any advance payment that has been made. (The law of England which refused this had, by mid-20th century, come into line.) Mention may be made of the negative and short prescriptions, so closely though not exclusively connected with contract. Very shortly, a person who fails to enforce his rights under contract for 20 years is prevented by the long negative prescription from doing so. Shorter periods such as three and six years apply to particular contracts, but these in the usual case merely add the need of writing to the burden of proof, without extinguishing the rights.

A useful conception is that of quasi contract. This means the obligation imposed, not by express agreement, but by force of circumstances. One example is *negotiorum gestio*, which means the obligation to make good expense incurred in intervening to help another in an emergency.

Sale of Goods.—The Sale of Goods Act, 1893, provides a short code of law for Scotland and England. Although many differences were reconciled in the act, a few, of varying importance, remain, such as the law pertaining to the effect of breach of warranty and condition. In English law the remedies of a buyer depend upon whether the seller's failure is concerned with a warranty or a condition. In Scotland the question is whether the seller's failure is a material failure. As regards forms, except in the case of hire-purchase (installment) contracts, there is no need for writing. (*See* also SALE OF GOODS.)

Movable Property.—Whatever has never had an owner may be taken and converted into property by *occupatio*, subject to some restrictive laws. Nondomestic animals are an example, even game, but poached game may be forfeited. *Accessio* is another mode: whatever is affixed to heritage or grows in it tends to become the property of the owner of the heritage. (Land itself cannot be acquired by *occupatio* since land in nobody's hands reverts to the crown.) But most property is acquired by transactions such as sale or gift or succession. By other transactions such as liferent, hire, deposit, and loan something short of property is acquired, usually possession, which is a concomitant of property. These transactions have their counterpart in heritage (immovable property), and liferent is of special importance there. A liferent cannot be created in favour of a person as yet unborn as, for example, by a bachelor in favour of his legitimate grandchild, who would, if this were attempted, become the owner.

Liferent confers rights upon the holder so extensive as to render

him virtually owner for life. Thus the liferenter is liable for discharge of burdens of all kinds upon the property not in the nature of capital payments; while he is entitled to use the liferented property as he pleases, except that he may not dilapidate it nor dispose of it for a period longer than the duration of his life. One important feature of the Scots law of property is the stress laid upon possession of the subject of a transaction. With some exceptions no security over movables can be created without actual or constructive delivery. Several important differences from English law follow. The bill of sale is unnecessary and unknown and the "floating charge" is incompetent. Security, too, by way of deposit of deeds is out of the question. Gift is, in accordance with the same principle, effected only by transfer of the thing given. And before 1893 the property in goods sold only passed on actual delivery.

Delict.—In modern usage delict signifies a wrong in its civil aspect and closely corresponds to tort in Anglo-American law. The basic rule of Scots law is that whoever injures another in his fortune, his person, or his good name either intentionally (delict) or through negligence (quasi delict) is liable to pay such damages as will, so far as practicable, restore the *status quo ante.* This is known as reparation. Damages are therefore given for injury, pain, damage to property, interference with trade, defamation, wrongful imprisonment, and the like. Injury to feelings, as through bereavement, is met by an award of solatium. This occurs where near relatives (father, mother, children) or husband or wife are killed.

The law of reparation rests upon the existence of culpa or fault and no liability attaches because of mere ownership of an object which causes damage. It is, too, only for the foreseeable results of negligence that damages are given. An important body of case law illustrates the liability of employers for the acts of their servants. In the law of defamation no distinction is drawn between written and spoken words. Utterance to the defamed person himself constitutes publication. It is not necessary in any case to prove special (particular and ascertainable) damage. There is no such thing as criminal libel, and holding up to mere ridicule is not actionable. Whatever the preunion law of Scotland, the crown was in postunion times immune from liability for wrongs done by its servants. In 1947, however, the Crown Proceedings Act introduced liability in most cases, thus probably restoring the Scots common law.

Civil Procedure, Diligence, and Bankruptcy.—All these differ greatly from their English counterparts. Civil procedure in the Court of Session and Sheriff Court is similar in many respects. If A has a claim against B it will first be made by the pursuer's (A's) solicitor against the defender, B. If the allegations are disputed or the case is not settled extrajudicially, the pursuer serves a summons on the defender, setting forth: (1) the sum or other remedy sued for; (2) a "condescendence" or statement of facts (averments) on which his claim is based and which he proposes to prove by evidence; (3) numbered pleas-in-law which set forth his legal contentions on the facts averred. The defender, if he means to defend the case, lodges defenses specifically answering the pursuer's averment and in turn stating his pleas-in-law. When the summons and defenses (known as "the pleadings") have been "adjusted" (*i.e.*, elaborated and revised), they are embodied in a document called a "closed record"; and at the subsequent inquiry evidence is restricted to proving the facts averred therein. Much importance is attached to relevancy; *i.e.*, the averments made must, if proved, entitle the party to the remedy sought. If they would not, then the case may be dismissed outright. If the case proceeds there is no opening speech except in a jury trial. The evidence may be heard by a judge or a sheriff substitute sitting alone (a proof); or in certain types of case, *e.g.*, action of damages for personal injury, by a judge and jury. In the Sheriff Court, the jury (7 in number as against 12 in the Court of Session) only hears actions of damages for more than £50 by employees against their employers, usually in respect of injuries sustained in accidents arising out of their employment. In a proof, when the evidence is complete, the parties' legal representatives make their submissions on the evidence to the judge, who may give an immediate judgment or take the case to *avizandum, i.e.*, for consideration, when he will give his judgment later. In a jury trial the speeches are made to the jury, who are then charged by the judge on the law applicable to the case. They retire to consider their verdict, and they will assess any damages. In the Sheriff Court the case is usually conducted throughout by a solicitor, though counsel (advocates) may appear. In the Court of Session only advocates, who must be instructed by solicitors, prepare the pleadings and have a right of audience. Both branches of the legal profession for centuries have provided free legal advice for poor persons in civil and criminal matters. After 1949, however, in civil proceedings, state provision for legal fees was available to persons of moderate means, often subject to a contribution by the assisted person.

Appeal from the decision or verdict lies: (1) in the Sheriff Court, first to the sheriff principal and thence to the Inner House of the Court of Session; or direct to the Inner House. In a jury trial, appeal is to the Inner House. (2) In the Court of Session, appeal lies from the lord ordinary, *i.e.*, the judge who first hears the case, to the Inner House. From the Inner House, appeal is to the House of Lords, whose decisions are binding on all inferior Scottish courts.

Diligence is the Scottish equivalent of execution and it takes several forms. Thus, for example, poinding (pronounced "pinding") means taking movables to satisfy the decree of the court. Arrestment involves directing the debtor of the judgment debtor to pay the latter's creditor direct. Adjudication means taking heritage in satisfaction.

Bankruptcy (technically "sequestration") is the state of officially recognized insolvency which follows usually upon unsatisfied diligence. It affects all property of the bankrupt in the British Isles. Various types of arrangements with creditors may avert the disaster. Statutory safeguards prevent abuse by way of fraudulent preference and the like. A bankrupt suffers civil disabilities ceasing on his discharge, which depends upon his conduct and upon satisfactory payments to the creditor. (*See* BANKRUPTCY.)

Criminal Law.—A crime is a wrong which, even if it only directly injures an individual, is held to be harmful to the community. Prosecution is therefore almost always a public function carried through by a public prosecutor. (*See* SCOTLAND: *Administration and Social Conditions: Justice.*)

Proof of a guilty intention on the part of the accused, as well as of an overt act, is necessary before a conviction can be obtained except where statute makes an exception or where the court has admitted the principle of vicarious responsibility. Such circumstances, therefore, as youth (no crime under eight), insanity, or compulsion will, subject to certain rules, render conviction impossible. The question of the responsibility of the insane is no more satisfactorily settled than elsewhere, but Scots law is more lenient in cases of insanity than English law. The English distinction between felony and misdemeanour is not made.

Nomenclature differs considerably from the English, and the same word (like embezzlement) may point to different offenses. Burglary and housebreaking are not distinguished; manslaughter is culpable homicide; receiving is reset; concealment of pregnancy and not concealment of birth is the crime and so on. The criminality of suicide lacks satisfactory warranty and D. Hume, the prime authority, shies away from pronouncing even upon attempt. In modern practice the public prosecutor may, but rarely does, prosecute an attempt as a breach of the peace. Almost always such cases, which usually involve insanity, are dealt with administratively after medical examination. The incidence of crime is different north and south of the border and the popular attitude to certain crimes also differs. Thus blackmail is not common in Scotland. And for many years in the earlier part of the 20th century Scottish juries could scarcely be brought to convict of murder.

Criminal Courts and Procedure.—Criminal procedure is either "solemn," *i.e.*, commenced by an indictment and tried before a judge and jury; or "summary," commenced by a complaint and tried before a sheriff or magistrate sitting alone. The High Court of Justiciary, the supreme criminal court, consisting of

judges of the Court of Session sitting as Lords of Justiciary, sits with one judge and a jury for trials; three or four of its judges decide appeals against conviction or sentence in cases tried either on indictment or summarily. The Sheriff Court tries cases in either manner. For summary cases, unless sentence is prescribed by statute, the sheriff may impose fines up to £150 and imprisonment up to six months. On indictment, he may sentence up to two years' imprisonment; and, if he considers that the crime requires more severity, he may remit the prisoner to the High Court for sentence. The burgh police courts and county justice of the peace courts can hear cases summarily and impose fines up to £25 and imprisonment up to 60 days.

Where a crime has been committed, the police report their findings to the district procurator fiscal, who may, and in all cases to be tried on indictment must, consult the crown counsel, at the Crown Office, in Edinburgh: they in turn being instructed by the crown agent. It is for the procurator fiscal or crown counsel to decide if a prosecution is to be brought, and, if so, in what court and whether on indictment or summarily. Proceedings are at the instance of the lord advocate or the procurator fiscal; the police do not prosecute. All investigation is private and potential jurors cannot be prejudiced by reading reports of earlier hearings, as could happen in England. An accused has no right to elect for trial by jury. A constable or citizen who sees a crime may arrest the offender without warrant; otherwise a warrant is obtained from a magistrate or sheriff.

Solemn Procedure.—In cases of serious crime the procurator fiscal presents a petition to the court setting forth the charge, and on this a warrant is granted. The accused, on arrest, is brought before the court and asked if he wishes to make a declaration. (Declarations, formerly common, are now rare.) Thereafter he may be granted bail. An indictment is served on him, specifying the charge and listing the witnesses and productions by which the crown proposes to prove the charge. At a pleading diet he intimates whether he pleads "guilty" or "not guilty." If "not guilty," the next stage is the trial. A jury of 15 is empaneled and the indictment read to them. There are no opening speeches: the evidence is led, first for the prosecution and then for the defense. The accused must be present throughout and is presumed innocent until proved guilty, the onus being on the crown to establish the charge beyond reasonable doubt. The proceedings are recorded in shorthand. At the conclusion of the evidence, the prosecutor addresses the jury first, the defense next, and the judge sums up. The verdicts, which can be by a majority, are "guilty," "not guilty," and "not proven"—this last when grave suspicion attaches to the accused but there is insufficient evidence to warrant conviction. There can be no retrial, even on a verdict of "not proven." The crown has no right of appeal against an acquittal.

Summary Procedure.—In minor offenses, a complaint is served on the accused narrating the charge, *e.g.*, careless driving. For certain statutory offenses, *e.g.*, traffic offenses, pleas of guilty can be made by letter and the accused be dealt with in his absence. If the plea is "not guilty," the evidence is heard by the sheriff substitute or magistrate, and the same presumptions and rules of evidence apply as in solemn procedure. After the parties have addressed the judge on the evidence he gives his verdict and sentences the offender. First offenders may not be imprisoned unless the court is satisfied there is no other appropriate way of dealing with them. If a fine is imposed, the court may allow it to be paid by installments and may not sentence to imprisonment for nonpayment without first inquiring into the accused's means.

Juveniles.—Special courts hear charges against children (aged 8–14), and young persons (14–17); and also deal with juveniles in need of care or protection, or who are refractory. If the accused is not legally represented his parent, guardian, or other relative may assist his defense. If found guilty he may be admonished; or put on probation; or fined (his parent is fined if he is a child); or detained for up to 28 days; or sent to approved school (up to age 17) or borstal (16–21). The court's paramount consideration is his welfare.

SCOTT, ALEXANDER (*c.* 1525–*c.* 1585), Scottish poet, one of the "last of the makaris" of the 16th century, a writer of lyrical freshness and technical skill. Nothing is known of his life, though he seems to have been familiar with Edinburgh and Dalkeith, and he is probably the "old Scott" referred to by Alexander Montgomerie, his younger poetic contemporary, in a sonnet dated *c.* 1584. All his extant poems, about 35 in number, are contained in the Bannatyne manuscript (1568; in the National Library of Scotland). Since Allan Ramsay printed a selection of his verse in his collection of old Scots poetry, *The Ever Green* (1724), Scott's reputation as a genuine minor lyric poet has been maintained. He left an amusing burlesque, *"The Justing and Debait vp at the Drum betuix William Adamsone and Johine Sym."* He also wrote a ceremonial and highly alliterative poem, *"Ane New Yeir Gift to the Queen Mary, quhen scho come first Hame, 1562,"* which gives an interesting reflection of early Reformation Scotland. His best work, however, is to be found in his love lyrics; these show a striking range of mood, from the tender to the coarse, and an admirable metrical suppleness and variety.

BIBLIOGRAPHY.—Scott's poems were edited by J. Cranstoun, Scottish Text Society (1896); by A. K. Donald, Early English Text Society (1902); and by A. Scott, Saltire Society (1952). *See* also C. M. Maclean, *Alexander Scott, Montgomerie, and Drummond of Hawthornden as Lyric Poets* (1915). (E. G. M.)

SCOTT, CYRIL MEIR (1879–), English composer and poet known for his piano and orchestral music, was born at Oxton, Birkenhead, on Sept. 27, 1879. In 1891 he began to study the piano at Frankfurt am Main, where he returned in 1895 for three years' training in composition with Ivan Knorr. During this period he became a friend of the writers Stefan George and Charles Bonnier and began to write poetry about 1900. He published translations of Baudelaire and two volumes of poems in 1910 and 1912. His early musical compositions, which he later destroyed, were performed at Liverpool, Manchester and Darmstadt; his reputation was established with a piano quartet (1901) and Second Symphony (1903). Under the influence of Claude Debussy and of oriental music, he later developed a freer harmonic and rhythmic style, notably in his sonatas for piano and for violin and piano. In 1913 *La Princesse Maleine*, the third of his overtures on plays of Maeterlinck, was given in Vienna. Between 1915 and 1948 he wrote several orchestral and choral works, including concertos for piano, harpsichord, violin and cello, a symphony, and a setting of Keats's *La Belle Dame sans Merci*. His opera, *The Alchemist*, was given at Essen in 1925. His chamber works include trios, quartets, quintets and numerous short pieces for the piano. His songs, written between 1903 and 1939, are settings of poems by himself, Ernest Dowson, Christina Rossetti, R. M. Watson and others. At the beginning of his career Scott established a reputation as one of the principal English composers known on the continent. His critical works include *The Philosophy of Modernism in Its Connection With Music* (1926) and *The Influence of Music on*

History and Morals (1929). He published his memoirs, *My Years of Indiscretion*, in 1924.

See A. E. Hull, *Cyril Scott: Composer, Poet and Philosopher* (1921).

SCOTT, DUKINFIELD HENRY (1854–1934), English paleobotanist, the leading authority of his day on the structure of fossil plants, especially those of the Carboniferous Period, was born in London on Nov. 28, 1854. His early education was by private tutors. In 1876 he graduated from Christ Church, Oxford. He became financially independent when his father died. Soon thereafter, he decided to study botany under Julius von Sachs (*q.v.*) at Würzburg, where, in 1882, he received his doctorate. He taught at University College, London (1882), and the Royal College of Science (1885); in 1892 he became honorary keeper of the Jodrell Laboratory at Kew. He was elected a fellow of the Royal Society in 1894. He left Kew in 1906 and settled at Oakley, where he died on Jan. 29, 1934.

Scott's early work was in plant anatomy, but his interests turned to paleobotany when he wrote, with William Crawford Williamson (*q.v.*), three memoirs on the organization of the fossil plants of the Carboniferous rocks (1895–96). In 1897 he described the complex cone of *Cheirostrobus*. His paper on *Lepidocarpon* (1901) showed that some Paleozoic lycopods bore "nascent" seeds, and the paper on *Botrychioxylon* (1912) revealed the presence of secondary wood in a Paleozoic fern. In 1904 Scott and F. W. Oliver announced their discovery that the seed *Lagenostoma* belonged to the fernlike *Lyginodendron*, thus bringing to light a new class of seed plants for which the name Pteridospermae was proposed. He wrote *Studies in Fossil Botany* (1900; 3rd ed., 1920–23) and *Extinct Plants and Problems of Evolution* (1924).

See notices in *Ann. of Bot.*, vol. xlix, pp. 823–840 (1935), containing a list of Scott's 154 publications, and in *Nature*, vol. cxxxiii, pp. 317–319 (1934), vol. clxxiv, pp. 992–993 (1954). (J. W. Tr.)

SCOTT, DUNCAN CAMPBELL (1862–1947), Canadian poet and man of letters, a member of the so-called "Confederation group" (*see* CANADIAN LITERATURE [ENGLISH]), was born in Ottawa on Aug. 2, 1862. He was the son of a Methodist minister, a Lincolnshire man who had emigrated to the U.S. in 1834 and to Canada in 1837. Scott was educated at various secondary schools in small communities in Ontario and Quebec and for two years beginning in 1877 at the newly founded Wesley Academy at Stanstead, Que. He then entered the civil service in the Department of Indian Affairs. From 1913 until his retirement in 1932 he was administrative head of the department. He did not begin to write poetry until about the age of 25 when he came under the influence of the Ottawa poet Archibald Lampman, with whom and with Wilfred Campbell he collaborated in writing a weekly literary causerie *At the Mermaid Inn*, which ran in the *Toronto Globe* from February 1892 to July 1893. On Lampman's death in 1899 Scott edited his friend's poems and wrote a memoir of him. Between 1893 and 1947 he published numerous volumes of verse: *The Magic House* (1893); *Labour and the Angel* (1898); *New World Lyrics and Ballads* (1905); *Via Borealis* (1906); *Lundy's Lane and Other Poems* (1916); *The Green Cloister* (1935); *The Circle of Affection* (1947). Among his prose writings are two volumes of short stories, *In the Village of Viger* (1896) and *The Witching of Elspie* (1923); two biographies, *John Graves Simcoe* (1905) and *Walter J. Phillips, R.C.A.* (1947); a one-act play and literary essays. Many of his poems and stories deal with Indian subjects and with the life of the habitant, but his love poetry and his nature poetry combine intensity and fire with accurate observation and a classical precision of form. He died in Ottawa on Dec. 19, 1947.

SCOTT, SIR GEORGE GILBERT (1811–1878), English architect of the Gothic revival and eminent Victorian, was born on July 13, 1811, at Gawcott, Buckinghamshire. He was apprenticed to a London architect and designed the first of his many churches in 1838, but his real artistic education dates from his study of A. W. N. Pugin's works on medieval architecture. The first result of this new study was the Martyrs' Memorial at Oxford of 1841.

Scott's international success in the competition for the new Nikolaikirche in Hamburg in 1844, with a design in 14th-century German Gothic, launched a career, the eminence of which now seems somewhat disproportionate to his architectural talents. Thereafter, however, he was one of the most prolific as well as the most successful exponents of the Gothic style throughout the High Victorian period. Among his best-known and most original works are the Albert Memorial (begun 1862–63) and St. Pancras Station Hotel (designed 1865), both in London. The restoration of long-neglected medieval cathedrals and abbeys, which was one aspect of the Gothic revival, was a controversial issue even in the 19th century, and Scott's treatment of such famous monuments as Ely, Salisbury, and Lichfield cathedrals, as well as Westminster Abbey, has been regarded with mixed feelings by subsequent generations. His own account of this work can be read in his *Personal and Professional Recollections*, published in 1879. Scott was knighted in 1872. He died in London on March 27, 1878.

See K. Clark, *The Gothic Revival*, 2nd ed. (1950).

SCOTT, SIR GILES GILBERT (1880–1960), English architect, designer of numerous buildings in the "traditional" style of the 20th century, was born in London on Nov. 9, 1880. Like his grandfather, Sir George Gilbert Scott (*q.v.*), he was a church builder, his greatest individual commission being for the new Anglican cathedral in Liverpool. The building of this massive Gothic structure in red sandstone, begun in 1904, spanned Scott's entire working life. He was knighted after the consecration ceremony in 1924.

Among his many secular works were the new Cambridge University Library (designed 1933), the new Bodleian Library, Oxford, and the new Waterloo Bridge, London. In 1944 he received the Order of Merit and in the same year was chosen as architect of the new House of Commons chamber, a simplified version of the one destroyed in World War II; the building was completed in 1950. Scott died in London on Feb. 8, 1960.

SCOTT, JAMES BROWN (1866–1943), U.S. jurist, publicist, and educator, one of the leaders in the international peace movement of the 20th century, was born of American parents on June 3, 1866, at Kincardine, Ont. Graduating from Harvard in 1890, he subsequently studied at Berlin, Paris, and Heidelberg. He devoted his life to expounding and advocating the application of law and justice between nations through arbitration and judicial settlement. Scott is remembered for the important part he played in establishing the Permanent Court of International Justice (1921) and the Academy of International Law (1914) at The Hague. He was one of the founders of the American Institute of International Law (1912) and of the American Society of International Law and its *Journal* (1906). This publication, of which he was editor in chief, was the first English-language periodical of its kind. He was author, among other works, of *Cases on International Law* (2nd ed. 1922), *The Spanish Origin of International Law* (1933), and *Law, the State and the International Community* (1939).

Dean of the Los Angeles (University of Southern California) and University of Illinois law schools and professor at Columbia and Georgetown (1896–1940), Scott was also editor of several casebooks, as well as of the *American Casebook* series, which was begun at his suggestion in 1908. During 1906–10 he acted as solicitor and technical adviser to the U.S. Department of State. He was delegate to numerous international conferences, including the 1907 Hague peace conference, where he urged the establishment of an international court of arbitration. Scott also served as secretary (1910–40) of the Carnegie Endowment for International Peace and as director of its division of international law (1911–40). He died on June 25, 1943, at Annapolis, Md.

SCOTT, ROBERT FALCON (1868–1912), British sailor and explorer, leader of the second expedition that reached the

South Pole, where he arrived on Jan. 17, 1912, only to find that Roald Amundsen had preceded him by little more than a month. Scott was born near Devonport, Eng., on June 6, 1868. Educated at Stoke Damerel and Stubbington House, Fareham, he became a naval cadet on HMS "Britannia" in 1881 and in 1883 a midshipman on the "Boadicea." Appointed full lieutenant by 1891, he was chosen in 1900 to lead the National Antarctic Expedition, taking up his duties in the "Discovery" with the rank of commander. Scott proved both an able and resourceful leader and a competent scientific investigator; on his return in 1904 he was promoted captain and the following year he was awarded the commander of the Royal Victorian Order. He continued in the navy, commanding successively the "Victorious," "Essex," and "Bulwark," until in 1909 he announced his intention of organizing another Antarctic expedition, for the purpose of continuing the work of the "Discovery" and of reaching the South Pole. Backed financially by the British and dominion governments, the expedition sailed in June 1910 in the "Terra Nova," and in November 1911 Scott, with four companions, began his southern sledge journey.

Delayed by bad weather, they reached the pole, where they found that they had been beaten by Amundsen. Sickness, insufficiency of food, and severe weather made traveling very slow on the return journey, and on Feb. 17, Petty Officer Edgar Evans died under the strain. A month later Capt. L. E. G. Oates, who was too ill to travel farther, walked out into a blizzard, hoping, by his sacrifice, to save his companions. But the weather prevented any possibility of advancing much farther, and four days later the party pitched the final camp. On March 29 Scott made this last entry in his diary:

> Everyday we have been ready to start for our depot *11 miles* away but outside the door of the tent it remains a scene of whirling drift. . . We shall stick it out to the end, but we are getting weaker, of course, and the end cannot be far. It seems a pity but I do not think I can write any more.

On Nov. 12 a search party found Scott's tent, containing the bodies of Scott, E. A. Wilson, and Lieut. H. R. Bowers, valuable geological specimens from the Beardmore glacier, and Scott's records and diaries, which gave a full account of the journey. A Mansion House fund was raised to provide for surviving relatives, and a polar research institute was founded (1920) in Cambridge to commemorate Scott's name and work. The rank and precedence of the wife of a knight commander of the Bath were conferred on Captain Scott's widow.

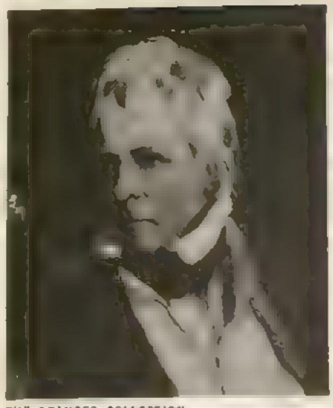
SCOTT, SIR WALTER, BART. (1771–1832), Scottish novelist, poet, and man of letters, the founder of the historical novel, and the first British novelist to become a great public figure, was born at Edinburgh, on Aug. 15, 1771, the son of Sir Walter Scott, a solicitor and writer to the signet, whose portrait is drawn by his son as Saunders Fairford in *Redgauntlet;* and of Anne Rutherford, the daughter of a distinguished professor of medicine at Edinburgh University. Scott liked to think of his remoter ancestry as including picturesque Border adventurers as well as feudal dignitaries, and he looked back with pride to Walter Scott of Harden, "Auld Watt," a 16th-century Border character who figured in ballad and story and whose grandson, Walter Scott, first laird of Raeburn, was the father of a Walter Scott ("Beardie") who was well known in Teviotdale and was Scott's greatgrandfather. In his memoir of his early life, written in 1808 (and included in J. G. Lockhart's *Life;* see *Bibliography*), he emphasized the colourful aspects of his Border ancestors, about whom as a child he had heard stories from his paternal grandmother and his uncle, Thomas Scott. Thus from early childhood his imagination was nourished by stories of an exciting past which conflicted with the staid Calvinist Whiggery of his father.

Early Life.—An attack of poliomyelitis at the age of about 18 months left him lame, and, after vainly seeking a cure from a variety of physicians, his parents sent him to stay for some time



THE GRANGER COLLECTION

SIR WALTER SCOTT. DETAIL FROM AN OIL PORTRAIT BY SIR EDWIN H. LANDSEER, 1824

with his paternal grandfather at the Border farmhouse of Sandyknowe. In his fourth year he spent about a year at Bath, again in search of a cure, before returning first to Edinburgh and then to Sandyknowe, where he divided his time between country expeditions (for he was by then healthy and vigorous in spite of his lameness) and avid reading of whatever poetry, history, and drama he could lay hands on. He had a remarkably retentive memory, and astonished visitors by his eager reciting of reams of poetry.

In 1778 Scott entered the high school at Edinburgh, and three years later, under the headmaster, Alexander Adam, attained fluency in reading Latin. He left in the spring of 1783 and spent six months with his aunt Janet at Kelso, where he further developed his love of the Border country and where attendance at the local grammar school improved his Latin. There, too, he read avidly "ten times the usual quantity of fairy tales, eastern stories, romances, &c" (*Memoir*) and discovered and delightedly read Bishop Thomas Percy's *Reliques of Ancient English Poetry.* His explorations of the neighbouring countryside developed that "love of natural beauty, more especially when combined with ancient ruins, or remains of our fathers' piety or splendour," which was to reflect itself in his writing.

In the autumn of 1783 Scott matriculated at the Old College of Edinburgh, and attended the usual Latin and Greek classes, though he never mastered the latter language. In May 1786 he began a five-year legal apprenticeship with his father but continued his miscellaneous reading and his country rambles. In 1788 he began to attend law classes at the university as well as classes in history and moral philosophy, and, having served his solicitor's apprenticeship, he decided to enter the higher branch of the legal profession and become an advocate. Between 1788 and 1792 he made a variety of friends among his fellow students (notably William Clerk; Adam Ferguson, son of the famous professor of moral philosophy; and John Irving). It was at Ferguson's house that Scott had met Robert Burns on the latter's visit to Edinburgh in the winter of 1786–87. He worked hard at his law studies but also led a sociable life, attending literary and debating societies and walking and dining with his friends. In July 1792 he qualified as an advocate.

It was during his student days that Scott's inherent love of conviviality, which was an important aspect of his character, first manifested itself. All his life he wanted to have his place in a hierarchy of social life in which equals as well as superiors and dependents played their recognized and accustomed parts. This wish was bound up with his sense of community, which, in turn, was bound up with his sense of history. He never practised extensively at the bar, but he learned a great deal about human nature and also about traits peculiar to the Scots character from his connection with the law.

The outbreak of the French Revolution appalled Scott by its wholesale scrapping of tradition and ruthless break with the past, and when war with France developed he hailed enthusiastically the enrollment of volunteers. In 1797 he eagerly joined the new cavalry corps, the Royal Edinburgh Volunteer Light Dragoons. He continued to indulge his taste for rural excursions and explored further into the Border country than he had yet done, making a notable visit to Liddesdale in the autumn of 1792 (a visit repeated annually for the next seven years) on which he got to know the country people and collected ballads. About the same time he was influenced by the new German Romanticism (*q.v.; see* also GERMAN LITERATURE), which had been introduced to Edinburgh by Henry Mackenzie (*q.v.*). The English "Gothic" novel also cast its spell. Scott's first published work, *The Chase, and William and Helen: Two ballads from the German of Gottfried*

Augustus Bürger, which appeared anonymously in 1796, shows his interest in the ballad temporarily turned toward the fashionable German vogue, as does his poor translation of Goethe's romantic tragedy, *Götz von Berlichingen* (1799).

Marriage.—By this time Scott had been through the one passionate love affair of his life, his unsuccessful courtship of Williamina Belsches, who was of a higher social class than that in which Scott's family moved. The affair seems to have begun in the early 1790s, and after many ups and downs it was ended in October 1796 by Miss Belsches' engagement to a rich young landowner, William Forbes. There is no doubt that this failure in love upset Scott deeply and permanently haunted his imagination. But his temperamental resilience, his active life, and his literary interests enabled him to avoid excessive brooding on his failure, and the publication of his two German ballad translations was soon followed by his ardent activities with the volunteers. He continued his eager reading of a great variety of literature and history throughout 1797, and in September made one of his characteristic expeditions through Tweeddale and over the Border to end up in the little watering place of Gilsland. There he met Charlotte Carpenter (Margaret Charlotte Charpentier), daughter of a former head of the military academy at Lyons, and of his much younger and lively wife. Mme Charpentier had run off to England with a young Welshman, had eventually come under the "protection" of Lord Downshire, and had returned to France when Lord Downshire married in 1786. Charlotte (b. December 1770) was educated in a French convent until 1787, when she went to England. She was baptized into the Church of England in May 1787 and apparently lived thenceforth with the family of Charles Dumergue, a successful French dentist in London, under the general supervision of Lord Downshire. When she met Scott she was visiting Gilsland with her companion, Jane Nicolson. She and Scott soon became engaged and were married in Carlisle on Dec. 24, 1797. It was on both sides a marriage of affection rather than passion; Charlotte had a gay and lively disposition but shared none of Scott's deeper interests. If, as Scott himself later admitted, their mutual feeling "fell short of love in all its forms," this was really what he preferred; "folk who have been nearly drowned in bathing rarely venturing a second time out of their depth," as he put it.

Literary Beginnings.—Scott and his bride set up house in Edinburgh. He was making a little money at the bar, his wife had brought him a few hundred pounds, and he had an allowance from his father. In 1798 they took a summer cottage at Lasswade, on the River Esk some six miles from Edinburgh. In April 1799 Scott's father died, while Scott and his wife were on a visit to London. Scott's meeting with M. G. ("Monk") Lewis (*q.v.*) in Edinburgh, 1798–99, and in London in the spring of 1799, encouraged another splash in the Gothic wildness of German Romanticism, which further postponed the emergence of his true literary interest and talents.

These at last manifested themselves with his edition of *The Minstrelsy of the Scottish Border* (3 vol., 1802–03). His view that the texts available to him represented oral corruptions of the original compositions led him to try to restore many of them to what he considered something closer to their original form; his methods of conflating, emending, "regularizing," patching, or simply adding to his texts are not today approved. Sometimes his efforts resulted in powerful and impressive poems, showing a sophisticated savouring of romantic detail which immediately betrays the hand of the "improving" editor. The last paragraph of his long introduction provides an important clue to the links in Scott's mind between patriotism, history, and literature: "By such efforts, feeble as they are, I may contribute somewhat to the history of my native country; the peculiar features of whose manners and character are daily melting and dissolving into those of her sister and ally. And, trivial as may appear such an offering, to the manes of a kingdom, once proud and independent, I hang it upon her altar with a mixture of feelings, which I shall not attempt to describe."

Scott had by now a wide circle of friends, including George Ellis, Richard Heber, that extraordinary self-taught prodigy John Leyden, James Hogg (*q.v.*), William Laidlaw, another ballad enthusiast, Lord Dalkeith, Lady Anne Hamilton, and many more. In 1804 he brought out an edition of the medieval romance *Sir Tristrem*, to which he added a "fytte" (or book) of his own composition. At last he found that he could not resist the temptation to turn minstrel in his own right, and what had begun as a ballad on the subject of a goblin page suggested to him by Lady Dalkeith grew into a full-length narrative poem, *The Lay of the Last Minstrel* (1805).

His appointment as sheriff-depute of the county of Selkirk in 1799 added £300 a year to his slender earnings at the bar and, with his father's estate, brought his income to respectable proportions. The duties of his sheriffship were light. The lord lieutenant of the county of Selkirk, who considered that he was spending too much time with the volunteers in Edinburgh, invoked the long-neglected rule that a sheriff should reside for at least four months of each year within his own jurisdiction, with the result that in 1804 Scott rented the pleasant house of Ashiestiel, on the south bank of the Tweed a few miles from Selkirk. In the same year his financial situation improved with the death of his uncle Robert Scott, who left him some property which he sold for £5,000. When the Scotts moved from Lasswade to Ashiestiel in the late summer of 1804 they had three children, two daughters (the elder of whom was to marry J. G. Lockhart; *q.v.*) and a son, Walter (b. 1801); a second son (b. December 1805) completed the family.

The Poems.—*The Lay of the Last Minstrel* was an immediate success and ran into many editions. It was followed by a spate of other narrative poems—*Marmion* (1808), *The Lady of the Lake* (1810; the most popular), *Rokeby* (1813), *The Lord of the Isles* (1815), and others. *The Lay* shows the influence in its rhythms of Coleridge's *Christabel*, but before long it settles down into the trotting octosyllabic couplets (varied occasionally with interspersed shorter lines rhyming with each other in ballad-metre style) which represent the norm of Scott's narrative verse. Scott wrote fast and without much artistic conscience; so long as he could keep the rhymes and the verse movement going he was content. He is at his best at describing settings (as in the opening of *The Lady of the Lake*) and sometimes in presenting fierce and rapid action; in love scenes and with sentiment generally he is at his worst. The description of the Battle of Flodden in *Marmion* has a fine heroic vigour and finely conveys a sense of doom. But sooner or later patches of mechanical padding are inserted to carry the verse on at all costs. The narrative is as a rule studiedly objective, but in *Marmion* Scott introduced preliminary passages of personal reminiscence. Scott also had a strangely melancholy lyric strain, which he learned from folk literature, found in occasional incidental lyrics introduced into the narrative poems as well as scattered throughout the novels.

Abbotsford and Publishing.—The success of *The Lay* meant that henceforth literature was to play an increasingly important part in Scott's life. His literary, legal, and social activities became increasingly lively; he was at the centre of a brilliant Edinburgh society. His country home, Ashiestiel, was only rented, and in the spring of 1812 he moved to a cottage on the small estate of Abbotsford (*q.v.*), near Melrose, and began the buying of land and the building of a country house there which was to absorb so much of his money. In 1806 he was appointed clerk of session, which meant his being in Edinburgh when the Court of Session sat. The arrangement was that the salary of £1,300 should go to the retiring clerk during his lifetime, but Scott would draw it on the former's death (Scott began drawing the salary in 1811). The expense of Abbotsford and other commitments necessitated his making ever more money. In 1802 Scott had given a loan to the Kelso printer James Ballantyne to enable him to remove his printing press to Edinburgh. In 1805 he became a sleeping partner in Ballantyne's firm, whose fortunes he at once began to push, trying to make it a condition with publishers of his own work that Ballantyne should do the printing. His own work by now included not only his poems but an increasing amount of miscellaneous and editorial writing: in 1808 his 18-volume edition of Dryden appeared, followed by an edition of Captain Carleton's *Memoirs* (1808) and of the Somers Tracts (1809–15), a 19-volume

edition of Swift (1814), and many other works. Publishing was soon added to printing, and James Ballantyne's irresponsible younger brother, John, was taken in as a partner. The firm started by publishing *The Lady of the Lake*, but Scott's enthusiasm for antiquarian, historical, and miscellaneous publications at this time led to the issuing of works such as *The Edinburgh Annual Register*, John Jamieson's *History of the Culdees*, H. W. Weber's edition of *Beaumont and Fletcher*, *The Poetical Works of Anna Seward*, among many others, most of which sold badly. From about 1810 almost everything that Scott wrote was in order to make money to meet financial obligations already incurred.

By 1813 the Ballantyne firm was moving rapidly to financial disaster. Faced with bankruptcy, Scott approached the publisher Archibald Constable (*q.v.*), who saved the situation by taking over £2,000 worth of Ballantyne's stock, on the condition that the publishing firm be wound up. A few months later an overdraft of £4,000 from the duke of Buccleuch again averted crisis, and by 1817 Scott was able to pull the printing business out of its indebtedness. Throughout this period Scott was leading a highly active social as well as literary life; he was still paying for Abbotsford as well as for enormous quantities of antiquarian relics for his collection there; and he was giving financial help to his brother Tom. His annual income was now £2,800 apart from the considerable profits of his writing. But he continued to spend more than he earned. The enormous success of *The Lady of the Lake* emboldened him to ask for and receive from Constable extravagant terms for *The Lord of the Isles*.

The Novels.—But already he was working on *Waverley*, originally projected in 1805 but left with only the opening chapters written. The greater verve and dash of Byron's narrative poems threatened to oust Scott from his position as supreme purveyor of this kind of literary entertainment, and he was looking for another vein. In the autumn of 1813 he accidentally came across the unfinished manuscript of *Waverley*, and completed it. It was published anonymously in July 1814 by Constable, with John Ballantyne & Co. doing the printing; Constable got half the profits, Scott the other half. Scott preserved his anonymity because he felt that it was not quite becoming in a clerk of session to write novels, then considered a rather frivolous form of literature. Leaving Edinburgh to buzz with excitement and speculation about *Waverley*, Scott set off at the end of July on a visit to the northern and western islands in the yacht of the lighthouse commissioner (R. L. Stevenson's grandfather). This six-week trip provided him with Scottish scenes he was later to use in novels. In April 1814 Constable asked Scott for an article on "Chivalry" for *Encyclopædia Britannica*, which he had just bought. "Chivalry" finally appeared in 1818, "The Drama" in 1819, and "Romance" in 1824.

Waverley was followed by *Guy Mannering* (1815), "the work of six weeks at Christmas"; *The Antiquary* (1816); two series of *Tales of My Landlord* (1816–19), which included *Old Mortality* and *The Heart of Midlothian*; *Rob Roy* (1818); a third series of *Tales of My Landlord* included *The Bride of Lammermoor* and *The Legend of Montrose* (1819). It was only after writing these novels of Scottish history that Scott, driven by financial need and the need to satisfy the public appetite for historical fiction that he had created, turned to themes from English history with *Ivanhoe*, *The Monastery*, and *The Abbot* (all 1820). *The Pirate*, set in the Orkneys, and *The Fortunes of Nigel* were published in 1822. Later novels included *Quentin Durward* (1823), *St. Ronan's Well* (1824), and, also in 1824, the last and one of the best of his Scottish novels, *Redgauntlet*. As a historical novelist dealing with medieval England, or France, or Germany, or the crusaders' Palestine, Scott showed a flair for highly coloured picturesque incident and situation. He also exhibited in varying degrees a sense of the poetry of history and an ability to project in terms of character and action something of the life and manners of the feudal ages. But he becomes a more complex and mature novelist the nearer he comes to his own time and country. *Ivanhoe* and *The Talisman* (the latter in *Tales of the Crusaders*, 1825) are colourful, somewhat theatrical, novels of rather obviously stylized period characters and action. *Quentin Durward*, *Kenilworth* (1821), and *The Fortunes of Nigel*, set respectively in the 15th, 16th, and 17th centuries, show a greater awareness of the complexities of the human situation and less disposition to be content with colourful surface action arising from the histrionic attitudes of somewhat cardboard figures who speak an invented antique dialect. Scott was nearly always better with minor and often low-class figures than with conventional heroes and heroines who had to act out the love story which the reader demanded but which never engaged Scott's real interest. He wrote too fast, and he wrote simply to entertain, and his novels often show a lack of artistic conscience. In dealing with picturesque aspects of the distant past, as well as on the one occasion, in *St. Ronan's Well*, when he dealt with the surface of life in his own day, Scott's imagination worked perfunctorily and did not draw on its deepest sources of inspiration. His real claim to greatness as a novelist rests on the "Scotch novels."

In dealing with the recent past of his own country Scott was able to find a fictional form to express the deep ambiguities of his own feeling about Scotland. One side of him welcomed the union with England and the commercial progress and modernization which it promised to bring; the other regretted bitterly the loss of Scotland's independence and the steady decline of its national consciousness and traditions. In novel after novel—most specifically in *Waverley* and *Rob Roy*—he introduces a polished and elegant representative of 18th-century British civilization, brings him for a short period into sympathetic contact with a representative of the older, heroic tradition, and then makes it clear that this representative of the heroic tradition is at best without function and at worst totally degenerate, so that the hero retires at the end to the "refined" modern society from which he came, enchanted with his adventure yet sobered into a realization that Highland chiefs are after all little more than freebooters in the modern world, where their tradition can have no place. In *The Heart of Midlothian*, one of the greatest of his novels, Scott looked at his country a generation after the Treaty of Union of 1707 and found characters and incidents which provided an "objective correlative" for his emotions about it. In *Redgauntlet* he showed with moving particularization how in late 18th-century Scotland (the period of his own childhood) the heroic Jacobite emotions of an earlier generation could find no realistic outlet in action. In *Old Mortality* he went to the 17th century to show the bitter meaning of the last full-scale flare-up of a really fighting Scotland. Scott's true heroes are not knights-at-arms but lawyers, farmers, merchants, and simple people who go about their business oblivious to the claims of the past.

Scott became a novelist by bringing his antiquarian and romantic feeling for Scotland's past and for a heroic age into relation with his sense that Scotland's interest demanded that she break with the past and look forward to a prudently commercial "British" future. Civilization must be paid for by the cessation of the old kind of individual heroic action: Scott welcomed civilization, but he also sighed after individual heroic action. This ambivalence of feeling gives life to his best novels. It also explains why Scott's finest dialogue is in the Scots speech he put into the mouths of his humbler characters and not in the stilted diction of his nominal heroes and heroines. The heroic characters in the end become histrionic or even ludicrous, and the humble or the prudent remain: Rob Roy is dismissed as a ranting exhibitionist and Bailie Nicol Jarvie, the canny merchant, survives into the future. And in *The Heart of Midlothian* the obviously heroic actions turn out to be merely criminal and sordid, and true heroism is found in the behaviour of Jeanie Deans, a simple Scottish lass. Scott's attempt to set himself up as the laird of Abbotsford, maintaining an almost feudal position with the proceeds of his finally disastrous publishing speculations and adorning a modern country house with an extraordinary collection of historical and pseudohistorical objects, symbolizes the ambiguity of his attitude.

Literary Success and Financial Failure.—It was not until 1827 that Scott formally revealed his authorship of the Waverley novels, but most people had guessed the truth. When he visited London in 1815, he was regarded as the greatest living Scotsman. Later that year he visited Flanders and the field of Waterloo, pub-

lishing his account of the trip as *Paul's Letters to His Kinsfolk* (1816). His arrangements with his publishers were becoming more involved; he was always in need of money, always arranging for money for books not yet written. Ballantyne and Co. still had stock they wanted taken off their hands, and Scott was using this in negotiations. He negotiated with William Blackwood and his London associate, John Murray (*qq.v.*), as well as with Constable, with the Ballantynes playing a confusing middleman's part. The first series of *Tales of My Landlord* was published by Murray, but *Rob Roy* and subsequent novels went to Constable. Both Scott and the Ballantynes seem to have played one publisher against the other. From 1818 Constable was publisher of the novels and the Ballantynes were Scott's agents. Scott, living expensively, and continually expanding his Abbotsford estate, was always asking Constable for payment in advance; he also raised loans from Ballantynes' printing business. Every new expense—travel, his daughter's dowry, the purchase of his son's commission—was met by bills discounted on work still to be done. Scott never guessed that all this time Constable and Co. was itself on the verge of bankruptcy.

In the years 1817 to 1819 Scott had frequent attacks of painful stomach cramp, but he went on doggedly with his writing. In February 1818 he was involved in the ceremonious discovery of the long-concealed regalia of Scotland. He received a baronetcy in March 1820, and in April his daughter Sophia married J. G. Lockhart in Edinburgh. In July 1821 he went to London for George IV's coronation, and in the summer of 1822 he was active in stage-managing the king's visit to Scotland. Just as Scott's Scottish poems and novels had made the Highlands popular haunts for tourists, so the king's appearance in a kilt led to a wave of kilt wearing and tartan enthusiasm. Scotland as it appears to the tourist and the foreigner is largely Scott's creation. In 1824 Abbotsford was finally completed and lavishly furnished, and in the Christmas and New Year season of 1824–25 Scott threw a great housewarming party. It was a happy season, and the last of its kind for Scott. In December 1825 he heard of the failure of Hurst and Robinson, Constable's London agents, and the subsequent chain reaction involved bankruptcy for both Constable and Ballantyne in January 1826. Scott's intimate involvement in both firms, so long his secret, now became public property; he was personally responsible for the Ballantyne liability. He faced the position with courage, surrendering to a trust his property and the profits of work both done and contracted for, and determined to work off the vast debt with his pen. He was allowed to keep the house and home farm at Abbotsford and his official salary of £1,600 a year. His wife died in May 1826.

Last Years.—Scott's chief nonfictional works in this last phase of his life were *The Life of Napoleon* (1827) and *Tales of a Grandfather* (1828), stories from Scottish history. His novels he kept on doggedly writing almost until the end with inevitably deteriorating quality. He resigned his clerkship of session in 1830 and was given a retirement allowance of £800 annually. The trustees allowed him to keep for himself the profits from *Tales of a Grandfather* and other nonfictional works, and he was far from living a life of poverty. But his health was breaking. His rash engagement in politics in Jedburgh on the antireform side in March 1831 was followed by a paralytic stroke in April; it proved temporary, like an earlier and less severe one in February 1830, but it was the beginning of the end. The government put a frigate at his disposal for a Mediterranean cruise in search of health, but the voyage—from October 1831 to June 1832—was marked by further strokes, and he was brought home to die. The sight of his beloved Border country briefly revived his awareness, and he died at Abbotsford, after a long period of semiconsciousness, on Sept. 21, 1832. He had no dying words for posterity, his alleged last words to Lockhart—"Be a good man"—being, as H. J. C. Grierson has shown, a deliberately pious fiction suggested to Lockhart by a lady correspondent. He was succeeded in the baronetcy by his son, Walter, on whose death (1847) the title became extinct.

Of the progress of Scott's tangled financial affairs, all that need be said is that the publisher Robert Cadell, after a variety of maneuvers, took over both Scott's liabilities and Scott's copyrights and made a fortune as a result. "I have paid Sir Walter Scott's debt and the debt of the estate of Abbotsford," Cadell wrote in 1848, "in a word a trifle of £7,600 and what is more surprising . . . the demand for his work continues." It continued until well into the 20th century, when critics of the novel began to demand of a novelist a greater awareness of the demands of fictional art than Scott had ever had the time to develop.

Scott invented the historical novel, and he invented the tourist's view of Scotland. Later readers and critics fastened on the high romantic aspect of his view of the past and ignored that disturbing double vision that resulted from the tension between his love of "the crowded hour of glorious life" and his shrewd awareness of its impossibility and even undesirability in the modern world. It is that double vision that modern criticism sees as the source of his greatest strength as a novelist.

BIBLIOGRAPHY.—*Bibliography and Editions:* G. Worthington, *Bibliography of the Waverley Novels* (1930); W. A. Ruff, *Bibliography of the Poetical Works* (in *Transactions of the Edinburgh Bibliographical Society*, I, 1937–38); J. C. Corson, *Bibliography of Sir Walter Scott, 1797–1940* (1943), a bibliography of books and articles about Scott and his writings. There are many collected editions of Scott's poems and of his novels. Of the former, the principal are the *Poetical Works* (1820), the *Poetical Works*, ed. by J. G. Lockhart (1833–34), both in 12 vol., and the *Poetical Works*, ed. by J. L. Robinson (1904). Editions of the Waverley novels include the Border Edition, 48 vol. (1892 ff.), the Centenary Edition, 48 vol. (1898); and the Edinburgh Edition, 48 vol. (1901–03). The novels and tales, with prefaces and notes by Scott, appeared in 48 vol. (1829–34). *Miscellaneous Prose Works* appeared in 30 vol. (1834–1871). *The Minstrelsy of the Scottish Border* was ed. by T. F. Henderson, 4 vol. (1932).

Correspondence and Biography: The standard edition of Scott's letters is that by H. J. C. Grierson *et al.*, 12 vol. (1932–37). J. G. Tait and W. M. Parker's edition of *The Journal of Sir Walter Scott* (1950) provides a better text than that of David Douglas (2 vol. 1890), although Douglas' annotations remain valuable. J. G. Lockhart, *Memoirs of the Life of Sir Walter Scott, Bart.*, 7 vol. (1837–38), a finely rendered picture of Scott and his environment, is not altogether trustworthy. It should be corrected by H. J. C. Grierson, *Sir Walter Scott, Bart.: a New Life Supplementary to, and Corrective of, Lockhart's Biography* (1938); John Buchan, *Sir Walter Scott* (1932) is derived from Lockhart but contains interesting critical perceptions. Hesketh Pearson's *Sir Walter Scott* (1954) is lively, and includes the findings of modern scholars, but is not an outstanding original contribution.

Criticism: Among critical works on Scott are: E. Muir, *Scott and Scotland* (1936); J. T. Hillhouse, *The Waverley Novels and Their Critics* (1936); W. L. Renwick (ed.), *Sir Walter Scott Lectures, 1940–48* (1950); D. Daiches, "Scott's Achievement as a Novelist," in *Literary Essays* (1956); D. Davie, *The Heyday of Sir Walter Scott* (1961); A. Welsh, *The Hero of the Waverley Novels* (1963). (D. Ds.)

SCOTT, WINFIELD (1786–1866), U.S. Army officer who served as a general in three wars and was the Whig candidate for president in 1852. Born near Petersburg, Va., on June 13, 1786, he entered the College of William and Mary in 1805. He was commissioned a captain of artillery in 1808 and fought on the Niagara frontier when the War of 1812 broke out. Although captured during this campaign, he was exchanged in January 1813 and fought through the rest of the war, rising to the rank of major general.

He took part in the battle of Chippewa (July 5, 1814) and was twice wounded in the battle of Lundy's Lane (July 25). After the war Scott remained in the military service, studied tactics in Europe, and eventually rose to become commanding general of the U.S. Army, a position he held from 1841 to 1861. In 1838 he supervised the removal of the Cherokee Indians from Georgia and other southern states to reservations west of the Mississippi River. Because of his emphasis on the military proprieties he was nicknamed "Old Fuss and Feathers," but the nickname should not be allowed to obscure his solid military talents.

During the Mexican War (*q.v.*; 1846–48) Scott commanded a seaborne invasion of Mexico that captured Veracruz late in March 1847. After victories at Cerro Gordo, Contreras, Churubusco, Molino del Rey, and Chapultepec, he entered Mexico City on Sept. 14, thus effectively ending the war. Scott was recalled in January 1848 by Pres. James K. Polk, with whom he had not been on good terms, to face a court of inquiry appointed to look into criticisms made of Scott's conduct of the campaign. The criticisms were later withdrawn and Scott was honoured by appoint-

ment to the brevet rank of lieutenant general.

A prominent Whig, Scott had been mentioned as a presidential candidate as early as 1839. At the Whig convention of 1848 his name was placed in nomination but he was defeated by Gen. Zachary Taylor. Four years later Scott won his party's nomination but lost the election to Franklin Pierce, mainly because the Whigs were divided on the slavery question. Scott remained a popular old soldier, and at the outbreak of the Civil War he commanded the U.S. Army until November 1861 when age forced his retirement. He died at West Point, N.Y., on May 29, 1866.

SCOTTISH LITERATURE. The term Scottish literature is difficult to define satisfactorily. It must include writing in Gaelic (*see* below); writing in Scots (*i.e.*, Lowland Scots or Lallans); writing in standard English; and writing in every possible degree of English and Scots combined. There is a tendency for the nationality of the Scottish writer to make itself felt, even when he is not using his own language. To this the English prose of Thomas Carlyle is a witness, as is also the Latin verse of George Buchanan; and even where the writer is not of fully Scottish blood it will sometimes be found that Scottish characteristics assert themselves, as they do in Byron. Although, therefore, works in Scots must claim most attention, especially in the period before 1600, works wholly or partly in English will also on occasion require consideration. The work of many Scottish writers forms part of English literature (*q.v.*); *see* also such general articles as BALLAD; SATIRE; etc., and articles on many of the writers mentioned.

IN SCOTS AND ENGLISH

Medieval Period.—Apart from poems of doubtful provenance and authorship (*e.g.*, the 13th-century romance *Sir Tristrem* with which Thomas the Rhymer's name is linked) and a few fragments quoted by later writers (such as the well-known *Quhen Alysandyr our King wes Dede*, included by Andrew of Wyntoun in his *Cronykil* of *c.* 1420), the earliest extant literature belongs to the second half of the 14th century. No doubt much earlier literature has been lost, as neither John Barbour's *Bruce* (completed 1376) nor *The Pistill of Susan* (written *c.* 1360; perhaps Northern English rather than Scottish; ascribed to Huchown of the Awle Ryale, but *see* HUCHOWN) can be called fumbling or primitive in technique. It is clear that these poems represent two distinct traditions, the former being in octosyllabic rhyming couplets, and having affinities with the French *chanson de geste*, and the latter having that alliterative rhyming stanza with concluding "bob" and "wheel" which apparently reached Scotland through the Middle English alliterative writers of the north and northwest and which became a characteristic Scottish poetic form. To the first tradition belong Andrew of Wyntoun's *Orygynale Cronykil* (completed *c.* 1420; publ. 1795), a metrical history of Scotland; and *The Buik of Alexander* and *Legends of the Saints*, which belong to Barbour's time and region if not to Barbour himself. The second tradition developed romance and fantasy rather than history, and includes Richard Holland's *Buke of the Howlat* (written *c.* 1450); the anonymous *Golagros and Gawane* (printed 1508); *Rauf Coilȝear* (written *c.* 1480); and shorter pieces such as *The Gyre-Carling*, William Dunbar's *Kynd Kittok* (if it is by Dunbar), and Robert Henryson's *Sum Practysis of Medecyne*. The rather dry, economical, unadventurous style of John Barbour (*c.* 1325–95), suited though it was to his own patriotic narrative, had little influence on later Scottish poetry; the *Bruce*, national epic in kind if not in value, is an isolated poem. The more flamboyant alliterative tradition, however, which in Scotland was readily employed not only for serious romance narratives but also for delightful "dremys and drevillings" such as *The Buke of the Howlat*, and for the wild ribaldry of *The Gyre-Carling* or *Sum Practysis*, proved more congenial and had a lasting effect well beyond the medieval period. Satire and fantasy, always strong elements in Scottish poetry, were well served by "thir mokking meteris and mad matere." The alliterative style was also valuable in forging a link between popular and sophisticated verse, which in Scotland was not broken to the same extent as it was in England after Langland's "rum ram ruf" gave way to Chaucer's decasyllabics.

The Makaris.—The great period of the makaris, or Scottish Chaucerians as they have been inadequately but inescapably labeled, may be taken to be *c.* 1425–1550. It includes the four chief pre-union poets: Robert Henryson (fl. 1475), William Dunbar (*c.* 1460–*c.* 1520), Gavin Douglas (*c.* 1475–1522), and Sir David Lyndsay (*c.* 1485–*c.* 1555); and to them must be added the author of *The Kingis Quair* (probably James I of Scotland, 1394–1437) and the author of *Schir William Wallace* (traditionally Harry the Minstrel, or Blind Harry, fl. 1470–95). Scottish poetry has never been so confident, so dexterous, or so varied as in the century that produced Henryson's *Testament of Cresseid*, Dunbar's *Tua Mariit Wemen and the Wedo*, Douglas' *Eneados*, and Lyndsay's *Ane Satyre of the Thrie Estaits*. The rough, swarming, precarious culture which nourished this literature has often the appearance of a rejuvenated medievalism rather than of a premature Renaissance. A fable by Henryson closes with its "moralitas"; Dunbar and Douglas continue and develop the conventional and centuries-old dream-allegory; Lyndsay is a reformer who remains within the church. What was not medieval, however—and it is an important element if we are to speak of rejuvenation—was the keen linguistic consciousness, the desire to expand and enrich the vernacular resources by all available means, which followed the political self-determination of Scotland in the 14th century and accompanied the Scottish writer's literary pride in the 15th. The elaborate "aureate" style in which the makaris often indulged has been criticized as artificial and excessive; but such excesses, which have their parallel in Elizabethan England, were a necessary stage in the development of a literary medium. The term "aureate" itself tells only half the story; Dunbar's *Goldyn Targe* cannot be called typical either of him or of his century's poetry. When Gavin Douglas, justifying his borrowings from other tongues in his translation of Virgil, speaks of his desire for "fouth of langage," he is revealing a very Scottish preference. Fouth—copiousness—demanded the encouragement of anti-aureate and popular elements as well as the aureate and the classical; of alliterative as well as Chaucerian tradition. Douglas' powerfully atmospheric descriptions of scenery and weather are almost bursting with words, and the etymological and idiomatic texture is far too rich for the restrictive implications of "aureate diction" to hold any meaning. This is even truer of works like *The Cursing of Schir John Rowll* and *The Flyting of Dunbar and Kennedie*, where commination and *estrif* induce the most uninhibited fouthiness of effect. (For the continuity of this

quality, *see* also *The Complaynt of Scotlande; Polemo-Middinia;* Sir Thomas Urquhart *passim;* Hugh MacDiarmid's *Scots Unbound.*)

Chaucer was to the makaris the eagerly acknowledged "rose of rethoris all," and there is no doubt that they gained from him an ideal of poetic utterance, a rhetoric or a diction, and metrical forms like the decasyllabic couplet used in *Schir William Wallace* and the Troilus stanza in rime royal (*q.v.*) used in *The Kingis Quair,* which taken together go far toward confirming the term Scottish Chaucerians. Scottish poetry, with its highly developed uncouthness, was fascinated by Chaucer's subtleties, just as its love of the incongruous almost succumbed to Chaucer's good sense and order. Nevertheless, his was only one influence among many. Both Chaucer and Dunbar were closely connected with the court circles of their day, and they addressed a courtly and educated audience; yet Dunbar refers with relish to farcical anonymous fantasies like *Colkelbie's Sow* which enjoyed widespread popularity beyond the court, and the grave Gavin Douglas shows familiarity with *Rauf Coilzear.* Lyndsay goes further toward meeting "John the Commounweill" (the allegorical representative of the common weal) halfway, and declares "... to colzearis (colliers), cairtaris (carters), and to cukis (cooks); /To Jok and Thome my rhyme sall be direckit." If the two extremely popular poems of Jock and Tom's festival merrymaking, *Christis Kirk on the Green* and *Peblis to the Play,* did in fact originate from James I or James V, as variously surmised, it would be another remarkable instance of this social give-and-take, perhaps not unexpected in a small country that had been only partly and haphazardly feudalized. "A man's a man for a' that" is a recurring statement in Scottish literature, representing a point of rest between outspoken social criticism on the one hand (Henryson, Lyndsay, Burns, MacDiarmid), and all the degenerations of the couthy and the pawky on the other hand (*Whistle Binkie* and Kailyard, for which *see* below). Apart, therefore, from questions of verse technique, we must supplement the Chaucerian influence by two additions: the vehement, practical, propagandist social satire of a Lyndsay, and (perhaps as a counterpoise) the extravagant daftness of a *Lichtounis Dreme,* with its impractical but equally Scottish occupation of "rostand straberries at ane fyre of snaw."

The golden period of the makaris had something of an aftermath in the accomplished but limited love poetry of Alexander Scott (*c.* 1525–*c.* 1585), Alexander Montgomerie (*c.* 1545–*c.* 1611), and William Fowler (1562–1612); the Italian translations and moral reflections of John Stewart of Baldynnis (*c.* 1550–*c.* 1605); the impressive plainness and sincerity of Sir Richard Maitland (1496–1586); and single outstanding lyrics from Alexander Hume (*c.* 1560–1609) and Mark Alexander Boyd (1563–1601). Here may also be mentioned the only surviving vernacular drama apart from Lyndsay's *Satyre*—the anonymous *Philotus* (*c.* 1600), a complicated romantic comedy, coarse in detail but vigorously written and certainly amusing.

The 17th Century.—With the union of the crowns in 1603 and the transference of the court to London, Scottish writing became increasingly anglicized; nor was much of it, in this century, of the first quality. Although James VI himself showed that he was capable of turning out a lyric in Scots, the new poets wrote almost exclusively in English. The best of these, William Drummond (1585–1649), was as "well-languaged" as his English contemporary Samuel Daniel, but his lyrics lack intensity and force, and one would gladly attribute the quiet un-English *Polemo-Middinia* to him, if only for its bold macaronic gusto. The lyrics of Sir Robert Ayton (1570–1638) and James Graham, marquess of Montrose (1612–50), are graceful without being distinguished. The sententious and indefatigable Sir William Alexander (*c.* 1567–1640) accomplished nothing that Fulke Greville and George Chapman had not done better. Vernacular poetry was kept alive in popular songs and ballads, and such literary verse as does guard the thin continuity of tradition between the makaris and Allan Ramsay is equally popular in character, with leanings toward the rustic, the homely, and the humorous (*see,* for example, Robert Sempill's *Life and Death of Habbie Simson, the Piper of Kilbarchan*). Whether grim and tragic as in the older ballads, or amusing as in *Habbie Simson,* this tradition was of the heart rather than the head, and indeed the absence of an intellectual and critical quality has been a besetting weakness in later Scots verse. The divorce of intellect and feeling was a natural result of the loss of Scots as a complete communicative instrument.

At this point it will be convenient to deal with the somewhat unspectacular history of Scottish prose, which covers (in its extant examples) the approximate period 1450–1630. The earliest work, dated 1456, is Sir Gilbert Hay's *Buke of Bataillis, Buke of the Order of Knichthood,* and *Buke of the Governaunce of Princes;* but these are translations. The first original literary prose appears in the theological writing of John Ireland (fl. 1480–90). The prose of these works, written in "the commoune langage of this cuntre," has not yet developed great variety or flexibility of construction. Early in the 16th century there was an attempt at a more plain, less latinized prose in Murdoch Nisbet's version of Wycliffe's New Testament, but the language is too southern to be quite successfully idiomatic. Some English influence is seen also in the 16th-century historical writings of John Bellenden, John Leslie, and Robert Lindesay of Pitscottie; and to a greater extent in works like John Knox's *History of the Reformation in Scotland* (*c.* 1567). These writers, however, had a good command of narrative, and Pitscottie and Knox had also the gift of style, which has made passages like Pitscottie's account of the Linlithgow apparition and Knox's interviews with Mary Queen of Scots justly famous. Almost as vivid as Knox's writing is the autobiographical *Historie of the Lyff of James Melvill,* which covers the second half of the 16th century. Standing by itself is the remarkable anonymous *Complaynt of Scotlande* (1548–49), interesting both as the work of an earnest and well-read Scottish patriot and as the first work of a Scottish experimenter in prose style, ranging from the most aureate "oncouutht exquisite termis" to the most common and onomatopoeic "domestic Scottis langage." The need to reach English readers is seen in the writings of James VI: the manuscript of his *Basilikon Doron* (completed 1598) is in Scots, but when published in 1599, it had been translated into English. William Drummond's *Cypresse Grove* (1623) is in careful, grave, mannered English; and not much Scots prose occurs after that date. A general justification for this turning to English may well be seen in the lucid and forceful 18th-century prose of David Hume, Adam Smith, James Boswell, and Tobias Smollett; though on the debit side must be placed the extreme difficulty of all attempts to revive vernacular prose, in a tradition so drastically severed. One particular justification is Sir Thomas Urquhart (1611–*c.* 1660), "the free'st spoke Scot of any," whose translation of Rabelais (1653) and extraordinary original works display a polymathic ornateness that would have cracked the molds of Scots as it did those of English.

The 18th Century.—While Scottish prose writers were preparing to challenge English on its own terms, and while the union of 1707 was suggesting an even closer cultural binding of the two countries than had been possible a century before, a contrary impulse was making itself felt in poetry. Almost in the year of the union appeared James Watson's first volume of *Choice Collection of Comic and Serious Scots Poems* (1706), which contained (among English pieces) vernacular poetry, from *Christis Kirk on the Green* and *The Cherry and the Slae* to recent verse like *Habbie Simson* and *The Blythsome Bridal.* This was followed by Allan Ramsay's *Ever Green* (1724) and *Tea-Table Miscellany* (1724 ff.), and by the later collections of David Herd, John Pinkerton, James Johnson, and George Thomson. These anthologies testify to a new national consciousness which began with a deliberate invocation of past achievements and eventually produced original work in the tradition of these achievements. As political identity was lost, cultural differences were increasingly recognized as significant. Educated speech was slowly but surely following written prose into anglicization, but in poetry, the heart of the language was still felt to beat, however faintly, as it was also in common speech and in the old songs and ballads which were being reprinted. Ramsay's own poetry, like that of Robert Fergusson (1750–74) and Robert Burns (1759–96), flourished on a union of these elements: the racy vigour of Scots speech, the musical lilt of the

songs, and the poetic forms and techniques, such as the Habbie Simson stanza, the humorous elegy, and the verse epistle, with which recent poets like the Sempills and William Hamilton of Gilbertfield had helped to solder the vernacular tradition. This new poetry lacked the range and also the intellectual power of the makaris' verse. Nevertheless, its qualities were notable and infinitely attractive: in the love songs "Duncan Gray" and "O, Wert Thou in the Cauld Blast"; in the voice given to the joy and pathos of "randie gangrel bodies" in "The Jolly Beggars"; in the unembittered descriptive tartness of Fergusson's "Auld Reikie" and "Butterfly." Burns excelled in both satires and love lyrics; in the former he carried on where Dunbar left off, and in the latter he crystallized the floating anonymous songs in forms at once popular and authoritative. Many traditions meet in Burns and his poetry reaffirms, perfects, and consolidates existing poetic modes and themes in a way which even in his own lifetime made it apparent that he was going to be a national bard. If any poet has deserved the epithet "life-giving" it is Burns, and yet by one of the ironies of literary history he proved a liberator for the poetry of England, but not for that of his own country.

ROBERT BURNS, ABOUT 1795

Among minor poets of the period, some of the best were women: Lady Grizel Baillie, Jane Elliot, Lady Anne Lindsay, and Lady Nairne. Of writers in English, James Thomson in *The Seasons* (1726–30) shares with Gavin Douglas the ability to make winter more impressive than summer, and produces some heavily drawn pictures of "Caledonia, in romantic view." Robert Blair's *Grave* (1743) shows a grim macabre relish not uncommon in Scottish poetry. William Falconer's *Shipwreck* (1762), admired by Burns, deserves mention; and James Beattie's *Minstrel* (1771–74) has historical importance as an early Romantic poem. Here must also be noted three popular and influential works of the time: John Home's tragedy, *Douglas* (1756), Scottish in theme but not in language; the cloudy grandeurs of James Macpherson's Ossianic fragments, which presented Europe with a vision of the noble Gael; and that "bosom favorite" of the young Burns, Henry Mackenzie's tear-strewn novel, *The Man of Feeling* (1771).

The 19th Century.—Mackenzie hailed the early works of Sir Walter Scott (1771–1832), who was destined to turn prose in a very different direction. The re-emergence of a vernacular prose, mainly within the novel and the short story, is one of the distinguishing features of this period. The writers may be divided into two groups: those who restricted Scots to dialogue and used English for the narrative, and those who employed a form of Scots, or at least a scotticized English, throughout. The former included Scott himself, James Hogg (1770–1835), Susan Ferrier (1782–1854), George Macdonald (1824–1905), Mrs. Margaret Oliphant (1828–97), William Black (1841–98), and R. L. Stevenson (1850–94); in the second and smaller group are John Galt (1779–1839), David M. Moir (1798–1851), and (in the 20th century) Lewis Grassic Gibbon. A book like William Alexander's *Johnny Gibb of Gushetneuk* (1871) contains so much dialogue as practically to belong to the scotticizers; it is, however, of interest mainly to philologists. The advantage of Galt's method in his *Annals of the Parish* (1821), of casting the book as the reminiscences of a Scots-speaking person, was that it secured a homogeneous tone, and the exact but not exaggerated Scots idiom is admirable. Scott, on the other hand, has the wider range that comes from contrast between English and Scots (as, most obviously, in "Wandering Willie's Tale" in *Redgauntlet*), though the faults of his English writing, and the restriction of his brilliant Scots dialogue to minor characters, sometimes make the result patchy and unsatisfactory, even if the great sweep of the story carries the reader through.

TITLE PAGE OF A 1793 EDITION OF JAMES THOMSON'S "THE SEASONS," A SPLENDID EXAMPLE OF SCOTTISH PRINTING AND ENGRAVING

A novel that begins "Come oot o' the gutter, ye nickum!" (George Macdonald's *Sir Gibbie,* 1879) is evidently of another type, and it may in fact be claimed as one of the many forerunners of the so-called Kailyard School of Fiction, which appeared toward the end of the century, and included Ian Maclaren (the Rev. John Watson, 1850–1907), S. R. Crockett (1860–1914), and James Barrie (1860–1937). (At the same time Fiona Macleod [William Sharp, 1856–1905] in his Celtic stories was creating the "Kailyard of the Gael.") The sentimental viewpoint that vitiates Maclaren's *Beside the Bonnie Brier Bush* (1894) and weakens Barrie's *A Window in Thrums* (1889), the cosy hypocrisies, the idealization of village and humble life, were pitilessly exposed in George Douglas Brown's *House with the Green Shutters* (1901). Brown's brutal tale, nevertheless, had its own exaggerations, those needed for its theme of tragic melodrama, and it had no more than a temporary effect in "sticking the Kailyarders like pigs," as one critic hoped. There is something in Kailyard, with its evasion of reality and its tendencies toward the sentimental and the pawky, still acceptable to the Scottish popular temperament.

The history of poetry in this period is very nearly a blank. Two poems of the supernatural keep up an ancient Scottish tradition: James Hogg's *Bonny Kilmeny* (1813) and William Bell Scott's *Witch's Ballad* (1875); there are some good vernacular lyrics by Scott, Allan Cunningham, and George Macdonald; but for the most part, the century after Burns saw merely the proliferation of the maudlin and the jocose in well-worn verse forms, the distortion and coarsening of Burns's gaiety and pathos, and the popularizing of everything in him that was less than first-rate. The widely read mid-century anthologies of verse called *Whistle Binkie: a Collection of Songs for the Social Circle* (1846) were the poetic equivalent of Kailyard, and their popularity is a comment on the poetic taste of the age. Indeed, during the second half of the century more interesting poetry was being written in English, by James Thomson (1834–82), Alexander Smith (1830–67), and John Davidson (1857–1909). What we feel to be lacking in Kailyard and *Whistle Binkie*—the impact of the contemporary world, of science, of industrialization, of the city, even (one must add) of ideas—gives strength and power to Smith's *Glasgow* (1857), to Thomson's *City of Dreadful Night* (1874), and to Davidson's *Testaments* (1901–08).

The 20th Century.—Prose fiction has developed, with minor variations, mainly within the Scott-Stevenson tradition. The "descriptions of the physical" on which Stevenson prided himself (though it was by no means his only gift), and the reliance on action rather than on psychological subtleties which we find in Scott, are continued in varying degrees in John Buchan (1875–1940), Neil Munro (1864–1930), and R. B. Cunninghame Graham (1852–1936), the last-named having shown in his *Scottish Stories* (1914) a nice use of Scots and a fine command of the macabre. More original are the picaresque, witty, and often fantastic narratives of Eric Linklater (1899–); the passionately written *Scots Quair* of Lewis Grassic Gibbon (James Leslie Mitchell, 1901–35), with a remarkable stylistic attempt to sink Scots idiom and vocabulary into the body of a richly descriptive English; the Celtic visionary quality in Neil Gunn (1891–); and the sharp character studies of Robin Jenkins (1912–).

Drama, revived to some extent by Barrie (*e.g., Dear Brutus,* 1917), discovered a more distinctively native voice in James Bridie (O. H. Mavor, 1888–1951); his entertaining plays, on an unusually wide variety of themes, combine the humorous, the ethical, and the supernatural in a very Scottish manner.

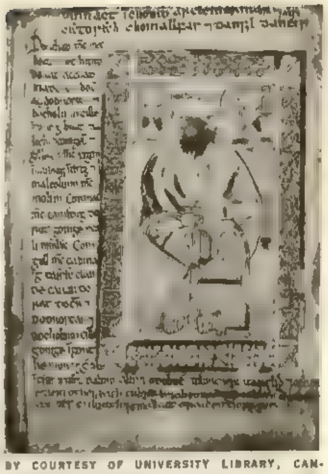
It is to poetry, however, that the term revival is more properly applied. The first steps toward a Scots verse that would more closely represent real experience were made by Stevenson (in *Underwoods*, 1887), Marion Angus (1866–1946), Charles Murray (1864–1941), Violet Jacob (1863–1946), Pittendrigh Macgillivray (1856–1938), Helen B. Cruickshank (1886–), and Alexander Gray (1882–). In the second decade of the 20th century the explosive personality of Hugh MacDiarmid (Christopher Murray Grieve, 1892–) made itself felt, as the centre and motive force of what has been variously called the Scottish Renaissance movement, the Lallans revival, and Synthetic or Plastic Scots. This movement, by re-expanding the Scots vocabulary after its post-Burns stagnation, complacency, and "hameliness," aims to restore the intellectual prestige of Scots and to create a medium capable of dealing with the objects and ideas of the modern world as well as with the perennial sources of lyricism. MacDiarmid himself has written the best lyrics since Burns; his sesquipedalian, polyglot, encyclopaedic, polemical, metaphysical verse has not aroused the same enthusiasm, but is interesting and significant. Other members of the movement include the humorous Robert Garioch (R. G. Sutherland, 1909–), the learned Douglas Young (1913–), the love poet Sydney Goodsir Smith (1915–), and the wry observer William Soutar (1898–1943). Of poets using English, Edwin Muir (1887–1959), with his meditative myth-haunted verse is the most distinguished; Norman MacCaig (1910–), W. S. Graham (1917–), George Mackay Brown (1927–), and Iain Crichton Smith (1928–) write with craftsmanship and force. In a class by itself is the delicate experimental poetry of Ian Hamilton Finlay (1925–). The Scottish sense of separateness is too real to be swamped, but English is dominant in prose writing and in educated speech, and the Scottish poet of the 20th century has been therefore like a shaman who must try out many disguises until he finds the one in which he can best prophesy and persuade. (E. G. M.)

MARK GERSON-CAMERA PRESS

HUGH MACDIARMID (CHRISTOPHER MURRAY GRIEVE), FOREMOST SCOTTISH POET OF THE EARLY 20TH CENTURY

IN GAELIC

It must be remembered that English or Scots was for long the language of a minority only in a Gaelic-speaking nation, and, although less than 2% of the population speaks Gaelic today, Gaelic literature still flourishes in Scotland. The early history of Scottish Gaelic literature, like that of the language, cannot be adequately considered in isolation from the literature and language of Irish Gaelic (*see* CELTIC LANGUAGES; IRISH LITERATURE). Kenneth Jackson demonstrated in his Sir John Rhŷs memorial lecture (1951) that Scottish and Irish Gaelic were identical until the 10th century, that they proceeded to diverge from the 10th to the 13th centuries, but that the language which he conveniently calls "Common Gaelic" survived as a living tongue until the 13th century. The conservatism of the literary classes ensured that there was a common corpus of literature even after the spoken languages diverged. Thus a distinct Scottish Gaelic period in literature can hardly be said to begin much before the 15th century. The Scottish parliament passed a law against the bards in 1457, when it was decided to take an inquisition of all "sornares, bairdes, maister-full beggers or feinziet fuiles." This law and some later ones were no doubt directed against the strolling bards, but governmental disapproval of the bards and of the Gaelic language and way of life grew; and the policy of centralization, and the gradual de-Gaelicization of the titled and moneyed classes, eventually deprived the Gaelic poets of their patrons, bringing both loss and gain to Gaelic poetry. But before looking at the literature of the modern Scottish Gaelic period we must take a glance at what lies behind it.



BY COURTESY OF UNIVERSITY LIBRARY, CAMBRIDGE

ILLUMINATED PAGE FROM "THE BOOK OF DEER," AN EARLY MANUSCRIPT CONTAINING GAELIC PASSAGES

Earliest Manuscript Remains.—The earliest document containing Gaelic matter which Scotland can claim is *The Book of Deer*, preserved in the University Library, Cambridge. This manuscript contains portions of the Gospels in Latin, written in an Irish hand, with illuminations. Inserted in the margins and blank spaces are later notes and memoranda partly in Latin, partly in Gaelic. The six Gaelic entries seem to have been made between 1131 and 1153, although some may be copies of earlier, perhaps traditionally preserved, grants of land and other privileges made from time to time to the monastery of Deer, Aberdeenshire. The scribes seem to have been trained, though somewhat imperfectly, in the Common Gaelic tradition of the period. Another strangely isolated survivor is the Islay charter of 1408. This charter, written in Gaelic, was granted by Donald, Lord of the Isles, to Brian Vicar Mackay of Islay. It is witnessed, and was very probably written, by Fercos MacBetha, one of the famous family of hereditary physicians of that surname.

These MacBeths, Beatons, or Bethunes had in their possession a number of important medical manuscripts, some of which are in the collection of Gaelic manuscripts in the National Library of Scotland. The O'Conachers, or McConachers, of Lorne were also hereditary physicians whose manuscripts are in part preserved. These manuscripts translate and paraphrase the works of such men as Bernard Gordon, Galen, Avicenna, and Hippocrates, while in their extra-medical digressions they show acquaintance with the works of Aristotle, Socrates, St. Thomas Aquinas, and others. Such various subjects as metaphysics, astronomy and astrology, theology, and music are treated. In medical matters the scribes sometimes give their own observations. These manuscripts date mainly from the 15th, 16th, and 17th centuries.

There are many other manuscripts, belonging to the common Scots-Irish tradition, which contain versions of heroic tales and sagas, poetry, ecclesiastical writings, and miscellaneous matter. One such, the Glenmasan ms. (no. liii in the National Library collection) was probably written *c.* 1500, but may derive from a 13th-century original. It contains the famous story of Deirdre (*q.v.*) and the sons of Uisneach. A part of the manuscript, containing the story of *Mesca Ulad*, dates from 1538. There is also a fragment of the most famous of Irish epics, the *Táin Bó Cúailnge* (ms. lix), and a Gaelic version of Lucan's *Pharsalia* (ms. xlvi), besides poetry written by Irish and Scottish bards.

But from the purely Scottish Gaelic point of view, the most important manuscript from this period is the *Book of the Dean of Lismore*, an anthology of verse compiled between 1512 and 1526 by Sir James MacGregor, dean of the diocese of Lismore in Argyllshire, and his brother Duncan. The poems fall into three main groups: (1) poems by Scottish authors; (2) poems by Irish authors: and (3) Ossianic ballads. The Irish poems belong mainly to the period 1200–1500. In the third group there are 29 poems, of which 4 belong to the Cú Chulainn cycle rather than the Ossianic one; these poems are attributed to various authors, for example, Oiséan, Fearghus File, Caoilte Mac Rónáin, and Conall Cearnach.

The poems by Scottish authors are interesting historically, linguistically, and poetically; their dates of composition range from *c.* 1310 to *c.* 1520. They give valuable evidence concerning aspects of contemporary society, and, being written in a semiphonetic spelling, partly based on the spelling of contemporary Scots, they

provide some evidence as to the pronunciation of Gaelic in the dean's time. Peculiarly Scottish features of pronunciation, morphology, and grammar can be detected. Many have a Perthshire setting, or are written to a MacGregor chief, but there are also, for example, poems to MacDougall of Dunollie, Macleod of Lewis, MacNeill of Gigha, and others. The bard best represented is Fionnlagh Ruadh, bard to John, chief of Clan Gregor (d. 1519). There are also three poems by Giolla Coluim mac an Ollaimh, probably a poet at the court of the Lord of the Isles. He laments the misfortune which had befallen this proud family in the late 15th century. Other poets are the dean of Knoydart (late 15th century), Duncan Campbell, the Good Knight of Glenorchy (who died at Flodden, 1513), Giolla Críost Brúilingeach, and two women, Aithbhreac Inghean Coirceadail (mid-15th century) and Isabella, countess of Argyll (probably the wife of the first earl). These last two are satisfying poetically, as is also the work of Giolla Coluim and of Giolla Críost.

The 16th and 17th Centuries.—Very little Gaelic poetry from the 16th century has survived, and most of it survived in oral tradition until the mid-18th century when it was written down. We can point to a few poems like *An Duanag Ullamh*, composed *c.* 1556 in honour of Archibald, fourth earl of Argyll; the lovely lament *Griogal Cridhe*, composed *c.* 1570; *Oran na Comhachaig*, in part no doubt composed in the second half of the 16th century; some poems by Sir John Stewart of Appin; and some by Niall Mór MacMhuirich. It is certain that the poetry recorded in the *Book of the Dean of Lismore* was not an isolated outburst; poetry was an integral part of the society of the time. Much must have been lost, both of the work of the professional bards and of the popular songs. Songs in the nonsyllabic, accented measures survive, again orally, from the earliest years of the 17th century, and it must be concluded that these forms have a previous history in the 16th century. This is the tradition which produced the work songs (*e.g.*, waulking songs used as an accompaniment to the fulling of cloth) better known from 17th- and 18th-century examples.

In 1567 the first book printed in Gaelic in Scotland appeared: Bishop John Carswell's *Foirm na Nurrnuidheadh*, a translation of John Knox's Liturgy. Carswell is modest about his ability to write Gaelic, but in fact his prose is in classical Common Gaelic, and resembles that of the 17th-century Irishman Geoffrey Keating. His prefatory epistle makes lively and pleasant reading.

The 17th century is a period of great interest in Gaelic Scotland. The political, ecclesiastical, and social structures of Scotland were gradually changing, and so was the relationship between the central government and the Gaelic area. Enough survives of the period's Gaelic poetry to show that there was a large number of poets of great talent. It is probably not a coincidence that the 17th century is also the great age of the waulking songs and of *ceòl mór*, or the classical music of the bagpipes. There seems to have been a diffusion of artistic talent such as is scarcely matched in any other period in Scottish Gaelic history. Some of the poetry and prose is contained in three 17th-century manuscripts. The first two are the *Black* and the *Red Books of Clanranald*, written by members (*e.g.*, Cathal and Niall) of the MacMhuirich family, hereditary bards to the MacDonalds of Clanranald. They were probably written for the most part in the 17th century, but contain poems by earlier representatives of this family of bards. Much of the two manuscripts is taken up with genealogical matter, and with an account of the Montrose wars and of the achievements of Alasdair MacDonald (Mac Cholla Chiotaich). From 18th-century accounts it is known that the MacMhuirich family had compiled other manuscripts, most of which were carelessly destroyed, although ms. xlviii in the National Library of Scotland is apparently a MacMhuirich poetry manuscript. Other hereditary bardic families were the MacEwens, bards to the Campbells, and the Ó Muirgheasáins, bards to the Macleods of Harris and Dunvegan.

The other important 17th-century Gaelic document is the *Fernaig Ms.*, compiled by Duncan Macrae of Inverinate between 1688 and 1693. This contains *c.* 4,200 lines of verse, mostly political and religious. The poets represented belong to the 16th and 17th centuries, although little work by the major 17th-century poets is given. The compiler's Jacobite and Episcopalian leanings are reflected in his anthology.

The two best-known poets of the 17th century are Mary Macleod and Iain Lom. The former, known as Màiri Nighean Alasdair Ruaidh (*c.* 1615–*c.* 1706), was closely associated with the households of the Macleods of Harris and Dunvegan. She seems to have been a member of the household of Rory Mór Macleod (d. 1626), and to have acted as nurse to successive generations of Macleod chiefs. Those for whom she had the greatest affection were probably Sir Norman Macleod of Bernera and Iain Breac Macleod of Dunvegan. Her earliest poem of certain date is the elegy for Roderick Mackenzie of Applecross (d. 1646), and one of her latest is the elegy for Sir Norman Macleod of Bernera (d. 1705). Her poems show deep personal emotion. Her imagery, though restricted in range, is sincere and telling, and her style is fresh and natural. She inherits much of the imagery of the bardic poets, but places it in a new setting, and her metres are the comparatively new strophic ones rather than the strict syllabic metres of the classical bards.

John Macdonald, known as Iain Lom (*c.* 1620–*c.* 1710), was related to the chiefs of the Keppoch Macdonalds, and took an active interest and an active part in the events of his time. His life spanned an eventful period in Highland history, and his poetry is full of comment on events. He composed poems about the battles of Inverlochy (1645), Auldearn (1645), and Killiecrankie (1689), a lament for the marquess of Montrose (d. 1650), a poem on the restoration of Charles II in 1660, several poems dealing with the Keppoch murder of 1663, an elegy for Sir James Macdonald of Sleat (1678), a song to William and Mary (1688), and a song bitterly opposing the union of the parliaments in 1707. He was a royalist and a fervent Macdonald panegyrist. As a Macdonald he lashes the Campbells; as a Roman Catholic he does the Presbyterians less than justice. But the breadth of his interest in national affairs is notable. His versification is less melodious than Mary Macleod's, and he has none of her tenderness and nostalgia. But he has that compression and concentration of expression lacking in so much later Gaelic poetry. This may derive in part from the style of the classical bards, as the directness of his utterance may from popular or folk poetry. He can achieve more at times by understatement than can the 18th-century poets by a plethora of epithets.

We can do little more than mention some other 17th-century poets of whose works interesting fragments have survived. Donnchadh MacRuaraidh was bard to Macdonald of Sleat, and his best-known poem consists of four calm resigned verses composed on the day of his death (*c.* 1630). The work of Alasdair MacKenzie (d. *c.* 1642) and of Murdoch Mackenzie (fl. 1650), both of Achilty, is represented in the *Fernaig Ms.* Alasdair is the *laudator temporis acti*; Murdoch sometimes shows lively interest in action and movement, as in his *An Làir Dhonn.* Roderick Morison, usually known as An Clàrsair Dall (the Blind Harper), was born in Lewis and became harper to Iain Breac Macleod of Dunvegan. Little of his work survives, but the strong texture and poetic intensity of his *Oran Mór MhicLeòid* and his *Creach na Ciadain* are remarkable. Dorothy Brown and Silis na Ceapaich (*c.* 1660–1729) are women poets of great talent, and with them may be grouped Mairearad Nì Lachainn (b. *c.* 1660) and Catriona Nic Ghilleathain (fl. 1700). Dorothy Brown's poem on Alasdair Mac Colla, and Silis na Ceapaich's laments for Lachlan MacKinnon and for Alasdair of Glengarry (d. 1721) are moving and artistic utterances. Eachann Bacach Maclean would be honoured for the one poem *A' Chnò Shamhna* (1648), even if no more of his work survived.

Four other poets mark, in various ways, the transition from the poetry of the 17th century to that of the 18th. They are Lachlan MacKinnon (Lachlann Mac Theàrlaich Oig), John Mackay (Am Pìobaire Dall), John Macdonald (Iain Dubh Mac Iain 'Ic Ailein), and John Maclean (Iain Mac Ailein). All four were born *c.* 1655–65. Much of their work lacks the economy of the best 17th-century poetry, and also its richness of imagery. John Macdonald's *Oran nam Fineachan* is not the worst in a series of tedious jingles which can be called clan verses, and which were popular with

18th-century poets. John Maclean shows a great interest in early Gaelic legend, and he composes amusing verses in a mock-heroic style. He also uses a mixture of verse and prose, as in his *Crosanachd Fhir nan Druimnean*. John Mackay's *Coire an Easa* is significant in the development of Gaelic nature poetry. Finally, bardic poetry continued to be composed into the 18th century by two members of the MacMhuirich family, Niall and Domhnall.

The 18th Century.—The 18th century has eclipsed the 17th partly because of the brilliance of some individual achievements, and partly because it is from the viewpoint of the 18th century that scholars often begin their retrospect of earlier Gaelic poetry. Practically no secular poetry in Gaelic was printed before 1751, and the bulk of earlier verse was recovered from oral tradition after that date. Interest in it was part of the antiquarian revival.

Much of the inspiration of Gaelic printing in the 18th century can be traced to Alexander Macdonald, or Alasdair Mac Mhaighstir Alasdair (*c.* 1700–*c.* 1770), who published a Gaelic vocabulary in 1741 and the first Scottish Gaelic book of secular poetry, *Aisheiridh na Sean Chánoin Albannaich* (*Resurrection of the Ancient Scottish Tongue*), in 1751. On both political and literary issues he showed virtues of independence and leadership which mark him out as a man apart among Gaelic poets of the century. During the '45 rising he was granted a captain's commission by Prince Charles Edward, and he seems to have regarded the rising as a crusade for the Highlands, or even for the Gaelic way of life. He rallied his fellow-Highlanders to the prince's cause with such poems as *Brosnachadh nam Fineachan Gaidhealach* (*Incitement to the Highland Clans*), and *Hi ri rì tha e tighinn*, a song of welcome to the prince. His poetical range is wide. His songs on the seasons must have been composed within 15 years of Thomson's *Seasons* (1726–30). Another notable nature poem is his *Oran do Allt an t-Siùcair*. His *Urnuigh do'n Cheòlraidh* (*Invocation of the Muses*) contains a mature statement of the aims of his art. His masterpiece, and longest poem, *The Birlinn of Clanranald*, is an extravaganza which is ostensibly a description of a voyage from South Uist to Carrickfergus. A fine poem in a quite different mood is the love poem *Moladh Mòraig* (*The Praise of Morag*). He also composed drinking songs and bitter satires. He has a rich vocabulary and a strong sense of technique.

Duncan Macintyre, or Donnchadh Bàn (1724–1812), was influenced in various ways by Macdonald. He published his poems in 1768, and signs of this influence can be seen in the subject matter and the metres, and sometimes in the phraseology of certain poems. But his individuality is not lost. The two men were very different in nature and in training. Macdonald had received a formal education; Macintyre could neither read nor write. Macdonald was ambitious, independent, and restless; Macintyre had none of these uncomfortable qualities. Macintyre fought on the Hanoverian side at the battle of Falkirk (Jan. 17, 1746), and later sang the praises of George III in *Oran do'n Rìgh*. He composed other soldiering songs, and various other set pieces on the clans, the bagpipes, and the Gaelic language, but his true subjects are wildlife and wild nature—the haunts and the habits of the red deer. He had been a forester on the Perthshire-Argyllshire borders in early manhood, and this is the setting of his greatest poems, *Moladh Beinn Dóbhrain* (*The Praise of Ben Dorain*) and *Oran Coire a' Cheathaich* (*Song to Misty Corrie*). These are remarkable for their emotional closeness to nature, their minute and objective detail, and their personal and lyrical quality. His most famous love song is addressed to his wife, *Màiri*. He is the best-loved of the Gaelic poets.

There were several other poets of note in the 18th century. John MacCodrum (*c.* 1693–1779) was appointed bard to Sir James Macdonald of Sleat in 1763, and his elegy for Sir James is one of his best poems. He had a good memory for genealogy and poetry, and was a known wit. He composed much humorous and satirical poetry. Rob Donn Mackay (*c.* 1714–78) was the bard of the Reay country, and used his gifts of observation and satire in commenting on the life of his district. Characters such as the miserly brothers of Rispond have a quality of universality. There is much social satire in his verse, and some delicate feeling for nature, as in *Cead Fhir Bhloguis do'n Fhrith*. William Ross (*c.* 1762–91) is the Romantic poet of the group. His poetry is emotional, subjective, and at times sentimental. An unhappy love affair occasioned several of his best poems, such as *Feasgar Luain* and *Oran Eile*. Another well-known poem is *An Suaithneas Bàn* (*The White Cockade*), composed on hearing of Prince Charles Edward's death in 1788. David MacKellar published his hymn on the Creation in 1752, but the greatest composer of Gaelic religious verse in the 18th century was Dugald Buchanan (1716–68), whose poems were published in 1767. His *The Day of Judgement* and *The Skull* are impressive and sombre, and show considerable imaginative power. Buchanan assisted Stewart of Killin in preparing his Gaelic translation of the New Testament (1767). Ewen MacLachlan (1773–1822), librarian of King's College, Aberdeen, transcribed many Gaelic manuscripts, including the *Book of the Dean of Lismore*, translated seven books of Homer's *Iliad* into Gaelic verse, and wrote Gaelic poems on the seasons.

19th and 20th Centuries.—A considerable amount of periodical literature was published in the 19th and 20th centuries. *An Gaidheal* is the lineal descendant of some of these periodicals. It has been joined by a quarterly, *Gairm* (1952 ff.). These periodicals contain the main volume of the Gaelic prose that we possess.

In addition there is a quantity of translation of religious works. There is a regular tradition of such translations since the 17th century. A translation of Calvin's Catechism was issued in 1631. Fifty of the psalms, together with the Shorter Catechism, appeared in 1659, Kirke's Psalter in 1684, and the Synod of Argyll's Psalter in 1694. Kirke's Irish version of the Bible in Roman type appeared in 1690. James Stewart's Gaelic edition of the New Testament was published in 1767, and John Stewart of Luss and John Smith of Campbeltown published a translation of the Old Testament (1783–1801). The complete Gaelic Bible was issued in 1807, and the first standard revision was that of 1826. Meantime many other religious translations were appearing, of works by Richard Baxter, Thomas Boston, John Bunyan, Philip Doddridge, and others, as well as volumes of sermons.

Some notable original prose works are Lachlan Maclean's *Adam and Eve* (1837), the Rev. Norman MacLeod's *Caraid nan Gàidheal* (1867), Donald Mackechnie's *Am Fear Ciùil* (1904), Angus Robertson's *An t-Ogha Mor* (1913), and the writings of Donald Lamont (1874–1958).

There was a dearth of vital poetry in the 19th century, when much laboured and mannered verse was composed. But there are partial exceptions, in some of the work of John MacLachlan of Rahoy (1804–74), Evan Maccoll (1808–98), Neil MacLeod (1843–1913), and Mary Macpherson (1821–98). John Morison (1790–1852), the poet-blacksmith of Rodel, composed some elevated and imaginative religious poetry. William Livingstone (1808–70) is full of rebellion and resentment, and he tried, without much success, to clothe Scoto-Norse history in poetic and dramatic dress. Angus Robertson's *Cnoc an Fhradhairc* (1940) is a hard poem to read, but it is rewarding in parts. Later a new movement to free Gaelic poetry from oppressive traditional shackles was inaugurated by Somhairle MacGhill-Eathain's (*q.v.*) *Dàin do Eimhir* (1943), George Campbell Hay's *Fuaran Slèibh* (1948) and *O na Ceithir Airdean* (1952), and Ruaraidh MacThómais' (Derick Thomson's) *An Dealbh Briste* (1951). In a style partly traditional and partly new is James Thomson's *Fasgnadh* (1953). Interesting new work in poetry has been published by Donald MacAulay and Iain Crichton Smith from 1956 onward.

Little of permanent value has been done in the drama. The art of the short story has been cultivated in periodicals and in Gaelic radio programs, notably by Finlay J. Macdonald, Colin Mackenzie, and Iain Crichton Smith. A collection by Smith, *Bùrn is Aran*, appeared in 1960. No fully adult Gaelic novel has appeared. The art of essay writing, however, has been pursued with distinction by Donald Lamont and others.

Collections of Gaelic Poetry.—From the mid-18th century onward a number of important collections of Gaelic poetry were made. One of the earliest was the Rev. Alexander Pope's (*c.* 1739). Jerome Stone collected Ossianic ballads and other verse before he died in 1756. The Rev. James Maclagan continued to collect material throughout the second half of the century, and his

manuscripts are in Glasgow University Library. The Rev. Donald MacNicol's collection also belongs to this period. Dr. Hector Maclean of Mull's manuscript dates from *c.* 1768. In 1776 Ronald Macdonald's *Eigg Collection* was published, and in 1786 John Gillies', based on Maclagan's. The notable enterprises of James Macpherson (*q.v.*), his *Fragments of Ancient Poetry* (1760), *Fingal* (1762), and *Temora* (1763), stem from this new collecting zeal, and in turn reinforce it. Macpherson's work is partly based on genuine Gaelic ballad sources, which can be elucidated, and partly constructed from borrowed English and Irish sources, and from his own imagination. But it is probable that we owe to Macpherson the collection and in some cases the preservation of valuable oral and manuscript material, as for example the dean of Lismore's manuscript. The Rev. Patrick Macdonald's *Gaelic Vocal Airs* was published in 1784. Important collections of the early 19th century were those of Alexander and Donald Stewart (1804), Patrick Turner (1813), and Alexander Campbell's *Albyn's Anthology* (1816–18). The movement continued with John MacKenzie's *Sàr-Obair nam Bàrd Gaelach, or the Beauties of Gaelic Poetry* (1841; new ed. 1904), Donald Macpherson's *An Duanaire* (1868), and the work of the two giants among 19th-century collectors, John Francis Campbell of Islay (1822–85) and Alexander Carmichael (d. 1912). Campbell's four volumes of *Popular Tales of the West Highlands* were published in 1860–62, and his *Leabhar na Féinne*, a great collection of heroic ballads, in 1872. The first installment of Carmichael's great work, *Carmina Gadelica*, was published in two volumes in 1900 (see *Bibliography*). The Rev. Alexander Cameron's *Reliquiae Celticae* (1892–94) made available in print much valuable manuscript material, such as the *Fernaig Ms.*, parts of the *Books of Clanranald*, and some of the Edinburgh manuscripts, with Ossianic and other material from various manuscript collections. A collection of Gaelic proverbs was published, with an English translation, by Donald Macintosh in 1785, and supplemented and enlarged by Alexander Nicolson in 1881; a new edition, edited by Malcolm MacInnes, appeared in 1951. Frances Tolmie's fine collection of Gaelic folk songs was published in 1911, and Margaret Fay Shaw's *Folksongs and Folklore of South Uist* in 1955. Beginning in 1872, there is the valuable series of *Transactions of the Gaelic Society of Inverness*, which has published much material from manuscript and oral sources. The periodical *Scottish Gaelic Studies* was launched in 1926.

SCOTTSBORO CASE, an incident in the history of U.S. criminal law that had international repercussions in the 1930s and resulted in two important decisions of the U.S. supreme court affecting criminal procedure. It originated in a fight between white and Negro youths on a freight train in Alabama on March 25, 1931. The white youths were thrown off the train, and in revenge they reported that the Negroes had raped two white girls who were also on the train. A mob formed in Paint Rock, Ala., and took nine Negroes off the train when it arrived there. The Negroes were arrested and jailed in Scottsboro, Ala., the county seat. Their trials began on April 6 and were completed in three days; eight were sentenced to death, the ninth to life imprisonment.

Communist organizations saw this case as an opportunity to dramatize oppression of the Negro in the U.S.; they took over the defense and gave the case international publicity. The executions were stayed pending appeal. In Oct. 1932 the supreme court reversed the convictions on the ground that the defendants had not had adequate representation by counsel (*Powell* v. *Alabama*, 287 U.S. 45). This decision stated an important new constitutional rule—that defendants in capital cases in state courts must be represented by counsel.

New trials were held in Alabama in 1933. Though one of the women involved testified this time that no rape had occurred, all of the defendants were re-convicted and sentenced to death. Again the convictions were appealed, and in April 1935 the supreme court again reversed the convictions, this time because Negroes had been systematically excluded from grand and trial juries in the county where the trials occurred (*Norris* v. *Alabama*, 294 U.S. 587). The defendants were again indicted, this time by a grand jury on which a Negro served.

After the first four trials resulted in convictions the state dismissed indictments of the others. Two of the prisoners were paroled in 1944 and another in 1951. The fourth, Haywood Patterson, escaped from prison in 1948 and two years later published his story of the case in *Scottsboro Boy*. The supreme court decisions in this case are landmarks in U.S. constitutional law and have had great effect in improving standards of criminal justice in the states. (C. H. P.)

SCOUT. The term "scout" generally is used in its military sense to indicate a member of a command who operates some distance ahead of the main body of troops for the purpose of obtaining information concerning the strength and position of the enemy. The scout is often described as "the eyes and ears of the army." Formerly scouts worked on foot or as horsemen, but in recent times they have done so from lightly armoured motor vehicles sometimes known as "scout cars." Navies have used small, fast craft for scouting purposes and aircraft also frequently act in this capacity. A scout is usually a uniformed member of the

armed forces, although in the 18th and 19th centuries—particularly in the American Indian wars—local inhabitants, with a knowledge of the language and local conditions, were frequently employed clandestinely and called scouts. Today such men are termed spies or intelligence agents, although the difference between these and true scouts may often be difficult to define. In World War II the term scout largely fell into disuse, the term patrol—indicating two or more men in a scouting role—being substituted. It is considered tactically unsound to use single scouts or single patrolmen.

Although scouts have been employed in all wars, the best known were probably those employed in the American Indian wars of the 1860s and 1870s. They were not uniformed members of the U.S. Army but were former fur trappers who had acquired a detailed knowledge of the country and agreed to serve the Army. Occasionally Indians were used as scouts to aid the troops against an enemy tribe. Among the best-known American scouts was William ("Buffalo Bill") Cody, who was flamboyant and colourful and had a gift for showmanship, although his actual importance probably was not as great as some of the others. Another well-known scout was Christopher ("Kit") Carson, who served as a guide for John C. Frémont, the famous "pathmarker" of the American West. Not so well known but possibly of greater importance was Jim Bridger, who had spent the greater part of his life in the mountains and on the Great Plains. Another was Frank Grouard, a mystery man of whom Gen. George Crook is said to have remarked that he would rather lose half his command than Frank Grouard. *See* also BOY SCOUTS; GIRL SCOUTS.

(E. I. S.)

SCRANTON, a city of northeastern Pennsylvania, U.S., the county seat of Lackawanna county, is 134 mi. W.N.W. of New York city and 110 mi. N.N.W. of Philadelphia. It is situated in the Lackawanna river valley on the western fringes of the Pocono mountains at an elevation of 752 to 1,770 ft. above sea level. Pop. (1960) city 111,443; standard metropolitan statistical area (Lackawanna county) 234,531. For comparative population figures *see* table in PENNSYLVANIA: *Population*.

Permanent settlement of the valley dates from 1788 when it was known as Slocum Hollow. In the next few years a gristmill, a sawmill and a charcoal furnace were built along the Lackawanna (Indian for "stream that forks"), but there was little development except for names: the village was called Slocum Hollow, Unionville, Harrison and Scrantonia before becoming Scranton in honour of the New Jersey family which established the Lackawanna Iron and Coal company there in 1840. George W. Scranton (1811–61) and his brother, Selden, bought a large tract (most of the present downtown business section) for $8,000 and began to smelt iron from local ores, using an anthracite hot-blast process. Persistent efforts by the two Scranton brothers and timely financial aid by their cousin, Joseph Hand Scranton, made the venture a success. By 1850 a rolling mill, a nail factory and a steel-rail works were in operation and transportation facilities had been provided. Scranton was incorporated as a borough in 1853 and chartered as a city in 1866.

Even before the iron ore was exhausted, the iron industry was overshadowed by the anthracite industry which has had a profound impact on the history of Scranton. The ethnic diversity of the area and the rapid population growth stemmed from the need for labour for the mines and allied industries. The first wave of immigration brought skilled English, Welsh and German miners but they were soon followed by the Irish, Austro-Hungarians, Poles, Russians and Italians. The wives of these immigrants provided a labour force that made possible the development of silk, apparel and other industries; Scranton has long been noted for its production of Nottingham lace.

Like the other cities of the anthracite coal region in northeastern Pennsylvania, Scranton has been forced to readjust its economy to the decline in the anthracite industry. Coal production valued at $196,908,000, or two-thirds of the combined total of mining and manufacturing in 1948, dwindled to approximately one-fourth of the total value a decade later. During the same period the percentage of workers employed in producing anthracite dropped from 33% to 14%, creating chronic unemployment of 15% to 20% of the total labour force. The "Scranton Plan" was developed to provide more jobs through industrial expansion. In 15 years after World War II over 30 plants and 3,000,000 sq.ft. of new floor space were made possible by the combination of community contributions, private financial and state aid. These new plants were either leased or sold to industries moving into the area, and the net income was reinvested in more plants. Textile, apparel, electronics and metal products manufacturers are the leading employers.

The economic readjustment brought on by the end of the war and the decline in the anthracite industry was also eased by Scranton's natural position as the centre of a large retail, wholesale and jobbing trade. Railroads, bus lines and airlines (at the Scranton-Wilkes-Barre airport, 6 mi. S. of the city) provide communication with all urban centres in the eastern United States. Three federal highways, and the northeastern extension of the Pennsylvania turnpike and the Pan-Canada international highway system provide the road transportation network of the area.

Educational facilities include the University of Scranton, established in 1888; Marywood, established in 1915; Lackawanna Junior college, organized as the Scranton Business college in 1894, becoming a junior college in 1959; a campus of the Pennsylvania State university commonwealth campus system (of two-year colleges), opened in 1921; the state school for the deaf; and the International Correspondence school, largest institution of its kind in the world. The public library has branches throughout the city and there is a county historical society.

The fine arts form a prominent part of the city's cultural life with a ballet guild, a philharmonic orchestra and an art league. The Everhart Museum of Natural History, Science and Art, located in Nay Aug Park, provides a focus for the appreciation of the fine arts. The park also contains zoological and horticultural gardens and a model mine open to the public. The Pocono mountains provide recreational opportunities as do the many mountain lakes and state parks within the area. (R. D. WI.)

SCRAP METAL. Used metals may be as important as ores as a source of metals and alloys for industrial use. The relative importance of scrap metal increases as the supply of metal in use accumulates and the supply of ores diminishes or the average grade declines. Scrap metals are particularly important in the production of steel, copper, lead, aluminum and zinc. Smaller amounts of tin, nickel, magnesium and precious metals are also recovered from scrap.

There are two distinct kinds of metal scrap: "old scrap" is metal that has been discarded after use and is returned to the metallurgical industry for reprocessing; "new scrap" is metal from manufacturing operations that has not been used in an end product and is therefore still in the process of manufacture. Metals produced from scrap usually are known as secondary metals as distinguished from primary metals, which are produced directly from ores. No such distinction is made for steel and precious metals. Steel is produced from a combination of scrap iron, pig iron and iron ores. Old scrap is gathered from widely scattered sources by scrap-metal or junk dealers and sold to secondary smelters. New scrap is concentrated in industrial areas and is usually purchased directly by secondary smelters. Many of the larger metal producers who produce secondary as well as primary metals buy back the new scrap from manufacturers to whom they sell primary metal.

Scrap usually is processed by sorting, blending and remelting to produce alloys similar to or more complex than those from which the scrap was derived. Old scrap in particular ordinarily is contaminated with foreign materials. Organic materials such as wood, plastic, paint or fabric can be burned off. Metallic impurities that are beneficial or inert usually are retained in the secondary ingot. Undesirable metallic impurities are diluted to tolerable proportions by the addition of pure metal or are removed by refining, *e.g.*, zinc is readily removed by distillation; lead can be refined by melting with a suitable flux. The price differential between scrap and refined metal permits only simple refining methods to be used. (H. W. S. C.)

SCREAMER, the name given to the three species of birds constituting the South American family Anhimidae, of the order Anseriformes. Although distantly related to ducks and flamingos, and like them gregarious and essentially aquatic in habits, they have marked anatomical differences. Perhaps the most noteworthy are the absence of a hooklike projection of the rib, the uncinate process—a deficiency unique among modern birds, but characteristic of *Archaeopteryx* (*q.v.*) and many reptiles—and the presence of a layer of small bubbles in the skin. The intestines

YLLA FROM RAPHO GUILLUMETTE

CRESTED SCREAMERS (CHAUNA TORQUATA)

are extremely long, the toes unwebbed and the bend of the wing is armed with a pair of spurs present even in new chicks.

The three species measure from 28–36 in. in length and are much alike in general appearance. All are black or gray above and pale gray or white below. The head is rather small and the bill chickenlike; the feet are disproportionately large. One species (*Anhima cornuta*) of tropical South America south to Bolivia and the Mato Grosso has a slender, recurved spine, three to five inches in length, protruding from the forward edge of the crown. The other two species, *Chauna chavaria* and *C. torquata,* are both crested. The former inhabits northern Colombia and western Venezuela; the latter southern Brazil and Argentina south to Mendoza and Buenos Aires.

Screamers are nonmigratory and frequent marshes and inundated grasslands where they subsist on vegetable matter. At times they may be found in flocks numbering thousands. They often sing in unison, their voices resembling loud trumpeting. A singular habit is that of soaring for hours in circles at immense altitudes, often uttering melodious cries.

The two to six white eggs are deposited in a shallow nest of rushes on marshy ground. Both sexes incubate the eggs and attend the young. (E. R. Be.)

SCREW, a cylindrical or conical member with a helical groove and ridge on it. (For the screws used to propel ships and airplanes, *see* Naval Architecture: *Resistance and Propulsion;* Aircraft Propulsion: *Propellers.*) The helix is found in a wide variety

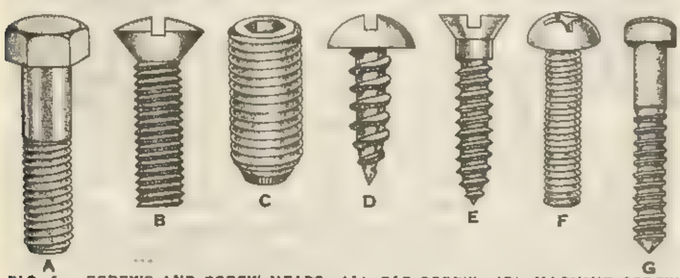

FIG. 1.—SCREWS AND SCREW HEADS: (A) CAP SCREW, (B) MACHINE SCREW WITH OVAL HEAD, (C) SET SCREW WITH HOLLOW HEAD, (D) SELF-TAPPING SCREW, (E) FLAT-HEAD WOOD SCREW, (F) PHILLIPS HEAD SCREW, (G) LAG SCREW

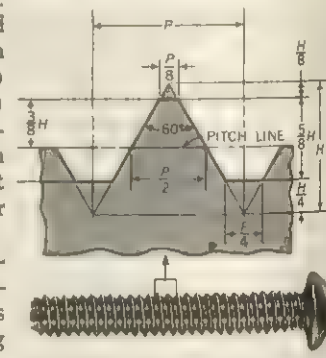
of applications, such as screw pumps (the first by Archimedes) and boring tools for metal, wood, soil, etc. In particular, a screw (without modifying adjective) is a threaded fastening device, without a nut; common examples are the cap screw, machine screw, set screw, wood screw, and lag screw (fig. 1). The cap screw is machine finished and made in sizes of about $\frac{3}{8}$ in. and larger; it generally has a hexagonal head, but may also be made with a hollow head such as shown on the set screw in fig. 1C.

Machine screws also are usually finished all over but are made in the smaller sizes—up to $\frac{3}{8}$ in. in diameter; various types of heads, nearly always slotted for a screw driver, are used, and patented heads, such as the Phillips head (fig. 1F), are common. Set screws are used to prevent relative motion between two parts which tend to slide over one another, as in fastening a small pulley to a shaft; they are obtainable with several different types of heads and points. Self-tapping screws, fig. 1D, are hardened screws designed to tap their own threads as they are turned into the hole; they are used to join thin sheets of metal, plastics, die castings, etc. Some types are applied with a screw driver, some with a hammer, and they are frequently made with a Phillips head. Wood screws are made in various diameters and lengths, in using the larger sizes, a hole is drilled first in order to avoid splitting the wood and to make the turning easier. A lag screw is a large wood screw, often used to fasten machinery and other heavy objects to wood. It usually has a square or hexagonal head so that it can be turned by a wrench.

Screw Threads.—A thread on the outside of a cylinder is an external or male thread; cut on the inside of a hole, as in a nut, it is an internal or female thread. The purpose in using threaded members may be: (1) to join two or more parts together; (2) to transmit power or force; (3) to obtain a mechanical advantage, that is, a large force from a small one; or (4) to transmit motion either rotary to linear or linear to rotary.



BY COURTESY OF BRITISH STANDARDS INSTITUTION B.S. 1580: 1962

FIG. 2.—SECTION (ABOVE) OF SCREW (BELOW) SHOWING BASIC FORM OF THE ISO/UNIFIED THREAD: P REPRESENTS PITCH AND $H = 0.866\ P$

Until about 1841 each manufacturer using threaded fastenings designed the threads for his own convenience. Fastening threads in the form of a sharp V had disadvantages: the sharp crests, being weak, broke off in small pieces, and the sharp root shape resulted in a high stress concentration that led to failure of the bolt. Failure of a screw or bolt resulted in delay, inconvenience, and expense because of difficulty in obtaining a replacement that would fit.

Trying to overcome these disadvantages, Sir Joseph Whitworth in 1841 proposed a fastening thread with rounded crests and roots with an angle between the sides of the thread of 55°; this became the British standard Whitworth thread used for general engineering. In 1864, in the U.S., William Sellers proposed a thread with flat crests and roots and a 60°-thread angle; this later was accepted as the U.S. standard. Toward the end of World War II a 60°-thread Unified Standard was recognized by the U.S., the United Kingdom, and Canada. This thread form (fig. 2) was accepted by the International Organization for Standardization (ISO). Publication of international standards for screw-thread systems in inch and metric units began in 1958.

Thus there is international agreement on some degree of standardization of the form of thread and general recognition of the desirability of international interchangeability. By interchangeability is meant, for example, that when a large number of bolts and nuts are made to a certain size and standard, any one of the nuts fits properly on any one of the bolts. In the Unified screw-thread standard there are several classes of fits possible. Class 1 is the loosest and cheapest, having the largest tolerances and allowances. Class 2 is about the average fit obtained by ordinary

production methods and is therefore commonest. Class 3, the closest fit and most expensive, would not be used without reason; the specified allowance between bolt and nut is zero. Intermediate classes of fits may be obtained by, for instance, using a class 3 nut with a class 2 bolt.

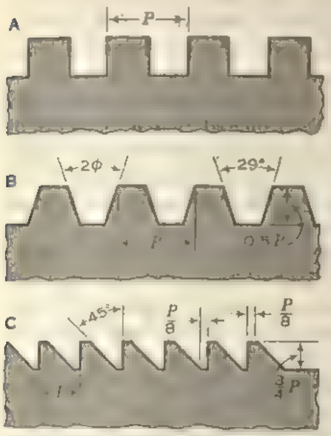


FIG. 3.—POWER SCREW THREADS: (A) SQUARE THREAD, (B) ACME THREAD, AND (C) BUTTRESS THREAD. P, PITCH; ϕ, PRESSURE ANGLE; AND 2ϕ, THREAD ANGLE

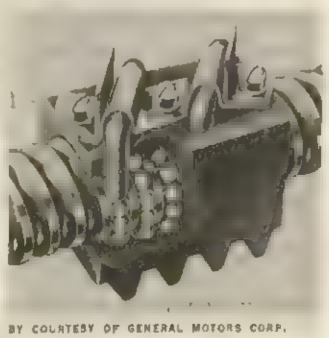
The largest diameter of a screw thread (*e.g.*, the outside diameter of an external thread) is called the major diameter; the smallest diameter (*e.g.*, the root diameter of an external thread) is called the minor diameter. The top of the external thread is known as the crest, while the crest of an internal thread mates with the root of an external thread.

There are several standard series of fastening threads. The coarse-thread series, with the fewest threads per inch for a particular size, is recommended for general use. The fine-thread series, which has more (and therefore finer) threads per inch, was developed for use in the automotive industry where strength and vibration resistance are important, and where the internal threads are in steel (not cast iron or other brittle material). The extra-fine-thread series of the American standard came about largely in response to the needs of the aeronautical industry. This thread has the maximum root diameter and strength; it is suitable for thinner walls; it is more resistant to loosening from vibration. Fastening screws with these threads are likely to be made of a heat-treated alloy for maximum capacity.

Threads for Transmitting Power.—One of the three forms of threads shown in fig. 3 is usually used for transmitting power or motion. Since the square thread must be cut on a lathe and the acme thread may be cut with dies, the square thread is more expensive to produce. Not only is the acme thread less expensive, but it permits use of a split nut with shims between the halves so that wear may be compensated for by removing shims. Ball-bearing screws (fig. 4) are used where it is advantageous to have a relatively low input effort and where arrangements with zero backlash are desirable. A worm driving a worm gear may be classified as a screw, often with a thread shape similar to the acme thread of fig. 3.



BY COURTESY OF GENERAL MOTORS CORP.

FIG. 4.—BALL-BEARING SCREW: BALLS ROLLING ON EXTERNAL AND INTERNAL THREADS COMPLETE THEIR CIRCUIT THROUGH TUBES AT TOP

The pitch P of a thread is the distance between corresponding points on adjacent thread profiles—in inches in some countries, millimetres in countries using the metric system. The number of threads per inch (or per millimetre) is the reciprocal of the pitch. The lead of a thread is the axial distance that the helix advances in one turn, or that a nut will move axially in making one turn. In a single-threaded screw, the lead is equal to the pitch; if two threads run parallel, the lead is twice the pitch (fig. 5). When high mechanical advantage is the prime requisite, a single-threaded screw is best. When high efficiency is essential, as in some worm drives, a large lead (*i.e.*, multiple threads) is necessary. An exception is the ball-bearing screw, which is said to have an efficiency of about 90% at very small leads. However, the efficiency of a screw-and-nut combination depends not upon the magnitude of the lead but upon the slope of the thread at the pitch helix, which is the tangent of the lead angle. The lead angle

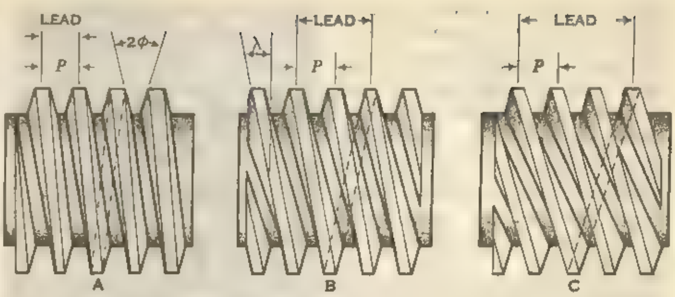


FIG. 5.—DIAGRAM SHOWING RELATION OF PITCH TO LEAD. ϕ, PRESSURE ANGLE; 2ϕ, THREAD ANGLE; AND λ, LEAD ANGLE

λ is the angle between a plane perpendicular to the axis of the screw and a line tangent to the pitch helix. The pitch helix has somewhat different definitions in different applications, but it is approximately at the mean diameter of the thread. The efficiency also depends upon the thread angle, the degree of lubrication, rubbing speed, materials, alignment, and workmanship in general. Some of these factors are accounted for by the coefficient of friction.

A value of the coefficient of friction equal to 0.05 is easily obtained in well lubricated worm drives; a value 0.15 corresponds to a situation at slow rubbing speed with the surfaces merely damp with lubricant.

Methods of Cutting Screw Threads.—The methods of cutting external threads may be described in six categories: turning, die threading, chasing, milling, rolling, and grinding.

Turning, a process still used occasionally, employs a single-point cutting tool of the same shape as the space between threads. The member to be threaded (that is, the work) is mounted in a lathe. The change gears on the lathe are arranged so that the work and the lead screw of the lathe turn with the proper relative speed to give the desired number of threads per inch on the work. If the work and lead screw turn at the same angular speed, the number of threads per inch on the work is the same as that on the lead screw; fewer threads are cut if the work turns slower than the lead screw, more if the work turns faster.

BY COURTESY OF (LEFT) NATIONAL ACME COMPANY (RIGHT) GREENFIELD TAP & DIE DIVISION OF UNITED-GREENFIELD CORPORATION

FIG. 6.—(A) THREAD-CUTTING DIE; (B) CIRCULAR THREAD CHASERS ON REVOLVING HEAD

Dies for cutting threads are made with internal cutting edges of the proper shape, size, and pitch (fig. 6A). Manual operation of thread dies is common for cutting small pipe threads on the job, but the dies are also used in machines, including automatic thread-cutting machines. On small threads and at slow speed, the die can be depended on to follow its own helical path with reasonable accuracy. On large threads and at high-production speeds, the relationship between die and work must be positively maintained.

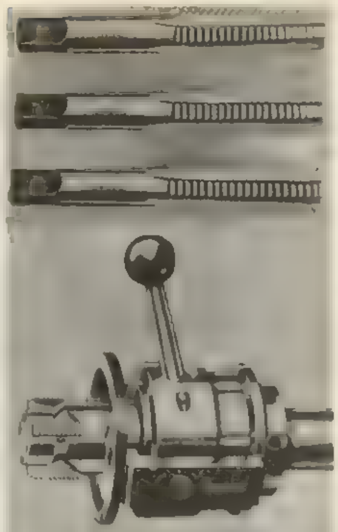
For machine cutting of threads, the rate of production is improved if the die automatically opens, allowing the work to be directly withdrawn (not unscrewed).

Chasing is the same in principle as die threading. The difference is in the configuration of the cutting edges. In one type, the cutting edges are on small cylindrical tools, as in fig. 6B; in another type the cutting edges are on flat pieces mounted with the tops of the cutting edges tangent to the root of the threads being cut.

Milling of threads is done on a standard milling machine, or one especially built for this work, using a milling cutter with a profile the same as the space between threads. In one type of machine, the cutters rotate on their axes and revolve about the work. Milling is useful in producing large, accurate threads.

Rolling produces threads by rolling the work between flat or cylindrical dies. Because the rate of production is high, the

process was first used to manufacture cheap stove bolts, but it has been improved until bolts and screws of superior quality can be produced in this manner. The die has hardened parallel ridges whose profile is the same as the desired thread profile and whose slope produces the correct lead of the screw. The shank to be threaded has a diameter approximately equal to the pitch diameter. As the blank is rolled between the dies under great pressure, it is indented and metal flows to the root of the die grooves (forming the crest of the thread). The cold working of steel during this process improves its strength, and the resulting surface finish is excellent.



BY COURTESY OF GREENFIELD TAP & DIE DIVISION OF UNITED GREENFIELD CORPORATION

FIG. 7.—TAPS: (ABOVE) HAND TAPS FOR CUTTING INTERNAL THREADS AND (BELOW) COLLAPSING TAP

The accuracy that may be obtained depends upon the accuracy of the dies and of the machine. When cylindrical dies are used, there are three of them, and of course the forces exerted by the rollers must be sufficient to cause the metal of the work to flow completely into the valleys of the roller threads.

Grinding can also be used to make threads by grinding with a wheel whose form matches the space between the threads. Grinding usually is used as a finishing operation, especially after heat treatment, for producing threads in hardened steel, and where cost is not a primary consideration.

Internal Threads.—Internal threads may be cut on a lathe or on a milling machine or ground by methods similar to those described for external threads. However, the most common method is by means of a tap (fig. 7). Hand taps may be adapted to low-speed machine work. The taper tap is used first, and it is the only one needed for a through hole. If it is desired to have good threads all the way to the bottom of a blind hole, the taper tap is followed by the plug tap and then by the bottoming tap. There are different kinds of collapsible taps suitable for high production: after they have completed the tapping, they automatically collapse and withdraw quickly. (V. M. F.)

SCREW PINE, the popular name for plants of the genus *Pandanus*, which are shrubs or trees of peculiar habit, having a main stem and a few branches at the ends of which is a tuft of long, stiff, narrow leaves closely arranged in three strongly twisted lines. The stem forms stout roots some distance above the ground; they grow obliquely downward to the soil and, because of the decay of the lower part of the stem, the plant is often supported merely by these strong prop roots. The ripe fruits are borne in very large spherical or cylindrical heads, which are often extremely hard. The genus is the principal one of the family Pandanaceae, a small family of monocotyledons, which is widely distributed through the tropics of the Old World, especially in the islands of the Malay Archipelago and of the Indian and Pacific oceans.

SCRIABIN, ALEKSANDR NIKOLAEVICH (1872–1915), Russian composer of piano and orchestral music, was born in Moscow on Jan. 6, 1872 (new style; Dec. 25, 1871, old style). He was trained as a soldier at the Moscow cadet school from 1882 to 1889 but studied music at the same time, taking piano lessons from S. Zverev. In 1888 he entered the Moscow Conservatory where he studied the piano with V. I. Safonov and composition with S. Taneev and A. Arenski. By 1892, when he graduated from the conservatory, he had composed the piano pieces which constitute his op. 1, 2, 3, 5, and 7. His first recital in St. Petersburg in 1894 led to a friendship with M. P. Belyaev, who not only published nearly all his later works but acted as his concert agent for recital tours in western Europe. In 1897 he married the pianist Vera Isakovich, and from 1898 until 1903 taught at the Moscow Conservatory. He then devoted himself entirely to composition, and in 1904 settled in Switzerland. After 1900 he was much preoccupied with mystical philosophy and his First Symphony, composed in that year, has a choral finale, to his own words, glorifying art as a form of religion. In Switzerland he completed his Third Symphony, *Le Divin Poème*, first given under A. Nikisch in Paris in 1905. The literary "program" of this work, devised by Tatiana Schloezer, with whom he had formed a relationship after abandoning his wife, was said to represent "the evolution of the human spirit from pantheism to unity with the universe ('The divine Ego')." Theosophical ideas similarly provided the basis of the orchestral *Poème de l'extase* (New York City, 1908) and *Prometheus*, which included a part for a colour organ projecting colours onto a screen during the performance, though this instrument was not used at the first performance (Moscow, 1911).

From 1906 to 1907 Scriabin toured the U.S. where he gave concerts with Safonov and M. Altschuler, and in 1908 he frequented theosophical circles in Brussels. In 1909 he was encouraged by the conductor S. Koussevitzky, who both performed and published his works, to return to Russia. About this time he was no longer thinking in terms of music alone; he was looking forward to an all-embracing "Mystery." This was planned to open with a "liturgical act" in which music, poetry, dancing, colours, and scents were to unite to induce in the worshipers a "supreme, final ecstasy." He even went so far as to proclaim himself a sort of messiah whose function it was to "sound the final chord of our race, reuniting it with the Spirit." He continued to give concerts, however, both in Russia and abroad, and in 1914 played under Sir Henry Wood in London. He wrote the poem of the "Preliminary Action" of the "Mystery" but left only sketches for the music. He died in Moscow on April 27 (new style; 14, old style), 1915.

Scriabin was a composer of the most sensitive, exquisitely polished piano music. His piano works include ten sonatas (1892–1913), an early concerto, and many preludes and other short pieces. Even his orchestral works create the impression of orchestrated piano music. An idolater of Chopin in his youth, he early developed a personal style. As his thought became more and more mystical, egocentric, and ingrown, his harmonic style—based on chords of fourths built up from the higher partials of the harmonic series—became ever less generally intelligible, and he failed to carry with him, as other harmonic innovators have done, enough admirers to establish his new idiom as a permanent, widely acceptable contribution to the language of music.

bine," in *Musique russe*, vol. ii, ed. by P. Souvtchinsky (1953); B. Pasternak, "Ich Kannte Scriabin," in *Melos*, no. 26 (1959). (G. AB.)

SCRIBE, AUGUSTIN EUGÈNE (1791–1861), French playwright, an outstanding dramatic craftsman who dominated the Parisian stage for some 30 years, was born in Paris, Dec. 24, 1791. He chose as his medium the *vaudeville*, a popular form of satirical comedy with rhymed and sung couplets, which he soon began to transform by replacing its conventional characters with characters observed from contemporary society (*Une Nuit de la garde nationale*, 1815) and by introducing elements of the comedy of manners, as in *Le Charlatanisme* (1825). His first real comedy was *Le Mariage d'argent* (1827), but though without sung couplets, this play retained the dramatic structure of the *vaudeville*. Scribe maintained that his sole aim was to amuse; addressing the Académie Française, to which he was elected in 1836, he denied that the theatre's purpose was to depict society.

He had a facile pen: working alone or with collaborators, he wrote over 400 theatrical works, including a ballet—*Manon* (1830)—and opera libretti: *Fra Diavolo* (1830), *Robert le diable* (1831), *Les Huguenots* (1836), and *Le Juif errant* (1852). His best-known plays are *Le Verre d'eau* (1840), *Bertrand et Raton* (1833), and *Adrienne Lecouvreur* (1849). His plays, which appealed to middle-class tastes and prejudices, brought Scribe a fortune. He died in Paris, Feb. 20, 1861.

SCRIBES, a group of Jewish scholars frequently mentioned in the Gospels, often together with the Pharisees and sometimes together with the high priests. The word "scribe" is used in the English versions of the New Testament to translate the Greek word *grammateus* (plural *grammateis*), which in turn was used to render the Hebrew word *sofer* (plural *soferim*). In early biblical Hebrew *sofer* usually designated an important court official, but during the first two-thirds of the period of the Second Commonwealth (from about 400 B.C. to A.D. 1), when Judaea was successively a province of the Persian, Macedonian, and Roman empires, *sofer* meant an interpreter of Scripture. It was in this capacity that Ezra (about 400 B.C.) was called a scribe. In the early part of the 2nd century B.C. Jesus ben Sirach, the head of a school of wisdom in Jerusalem, celebrated the intellectual and moral preeminence of the *soferim* or scribes (Ecclus. 38:24–39:11).

During the last three centuries before the beginning of the Christian era the *soferim* were the professional interpreters and teachers of biblical law and ethics. Since the Jewish community enjoyed cultural autonomy under foreign rule, it was permitted to govern itself by its own constitution (called *politeia* in the ancient Greek sources), namely the Pentateuch. However, the Mosaic laws required interpretation and expansion to meet the needs of this later age and the work of interpretation was undertaken by the *soferim*. The two leading religious-political parties, the Pharisees and Sadducees, both had their professional scholars or scribes, but as the Pharisees enjoyed greater influence among the Jews as a whole, it was the Pharisaic scribes whose interpretation of the law was considered authoritative by later rabbinic scholars (*see* JEWISH SECTS DURING THE SECOND COMMONWEALTH). It is the Pharisaic scribes who are meant in most of the Gospel references to *grammateis*. It should be noted also that the Gospels treat this word as synonymous with *nomikoi*, "jurists," and *nomodidaskaloi*, "teachers of the law" (*i.e.*, biblical law). The chief Jewish legislative and judicial body meeting in Jerusalem from about 200 B.C. to A.D. 70, known as the great Sanhedrin (*q.v.*), was made up of scribes of the Pharisaic party as well as the scribes and priests of the Sadducean party.

Which party was in the majority throughout this period is not known, but sources indicate that on certain matters, the opinions of the Pharisaic scribes prevailed. However, there was a difference in the usage of the word "scribes" between the Jewish and Christian writings of the first two centuries A.D. The rabbinic sources of this period apply the word "scribes" (*soferim*) to the biblical interpreters and jurists of the period between Ezra and their own time, while the Pharisaic scholars or rabbis of their own period are generally called sages (*hakamim*), though they performed the same functions as the *soferim*. The latter term was usually applied in the Hebrew writings of the first two centuries A.D. to less eminent persons, such as writers of legal documents, copyists, notaries, and teachers of elementary schools. When the Gospels speak of scribes (*grammateis*) as contemporaries of Jesus, they mean the jurists and teachers who had earlier been called *soferim* but were now generally called *hakamim*.

The chief functions of the scribes throughout the greater part of the period of the Second Commonwealth were: (1) to interpret the biblical law and to provide new legislation by the construction of the written text or on the basis of the tradition of the elders (*i.e.*, the oral law); (2) to give instruction in all fields of knowledge relevant to the study of Scripture; (3) to act as legal advisers to judges and those who administered the law.

See Emil Schürer, *Geschichte des jüdischen Volkes im Zeitalter Jesu Christi*, 3rd ed., vol. ii, pp. 312–328 (Eng. trans., *History of the Jewish People in the Time of Jesus*; 1961); G. F. Moore, *Judaism*, vol. i, pp. 39–40. (RA. MS.)

SCRIBNER, the name of a family of U.S. publishers, descended from settlers in Norwalk, Conn., in the 1600s; the name, originally spelled Scrivener, was changed to its present form after 1742. Charles Scribner (1821–1871), founder of the firm, was born in New York City on Feb. 21, 1821, and was graduated from the College of New Jersey (Princeton) in 1840. He began publishing in New York as a partner of Isaac D. Baker in 1846. Upon his death, in Lucerne, Switz., on Aug. 26, 1871, the business was carried on by his three sons and in 1878 the firm was renamed Charles Scribner's Sons.

From the beginning the Scribner list was distinguished for its theological and philosophical works; in the latter part of the life of the first Charles Scribner the firm also began to publish reprints and translations of English and European works. The second Charles Scribner (1854–1930), president of the firm from 1879 to 1928, further diversified the list, and under the Scribner imprint appeared works by many of the most eminent writers of the time, including, among Americans, Henry James, George W. Cable, and Theodore Roosevelt, and among British authors, Robert Louis Stevenson, George Meredith, Rudyard Kipling, and John Galsworthy. Among the periodicals published by the firm were *Scribner's Monthly*, founded 1870, and *St. Nicholas*, founded 1873, both sold in 1881 to the Century Company (*Scribner's Monthly* being renamed *The Century Illustrated Monthly Magazine*); and *Scribner's Magazine* (1887–1939).

See Roger Burlingame, *Of Making Many Books* (1946), a centennial history of the firm; G. W. Schuyler, *Colonial New York* (1885), vol. ii, for the genealogy of the Scribner family.

SCRIPPS, EDWARD WYLLIS (1854–1926), U.S. newspaper publisher, who inaugurated the newspaper "chain" in the U.S., was born on a farm near Rushville, Ill., June 18, 1854. Educated in the district school and a private one conducted by his half sister Ellen, Scripps in 1872 joined the staff of the *Detroit Tribune*, then partly owned and managed by his half brother, James Edmund Scripps, who in 1873 started the *Detroit Evening News*, on which Edward was a reporter and finally city editor. He left his job in 1877 to tour Europe with his half brother George, and on his return began the *Cleveland Penny Press* in 1878. Buying or establishing papers, first in the Midwest and later on the West Coast, Scripps before his death expanded his chain to 34 newspapers in 15 states. (*See* NEWSPAPER: *United States: "Chains" and Consolidations*.) His papers were low-priced (originally penny papers), written for the "95 per cent," *i.e.*, the common people, politically independent, liberal, and prolabour.

In 1897, with George and Milton Alexander McRae, who were partners in the chain, he organized the Scripps-McRae Press Association, ultimately combined with another independent service as the United Press. He also organized the Newspaper Enterprise Association, the first newspaper syndicate created to serve a chain of newspapers. In 1922 he transferred his interests to his son Robert. Scripps died on board his yacht in Monrovia Bay, Liberia, on March 12, 1926.

BIBLIOGRAPHY.—Gilson Gardner, *Lusty Scripps* (1932); N. D. Cochrane, *E. W. Scripps* (1933); and *Damned Old Crank* (1951), a collection of Scripps's autobiographical writings, edited by Charles R. McCabe.

SCROFULA, the general name formerly given to tuberculosis (*q.v.*), "scrofulous," "strumous," and "tuberculous" being nearly interchangeable. The particular characteristics associated with "scrofula" have, therefore, varied at different periods when the real nature of the disease was misunderstood; but essentially what was meant was tuberculosis of the bones and lymphatic glands, especially in children, and it is in this sense that the word survives. The old English popular name was "king's evil" (*q.v.*), so called from the belief that the sovereign's touch could effect a cure.

SCROGGS, SIR WILLIAM (*c.* 1623–1683), lord chief justice of England from 1678 to 1681, presided over the trials of those accused of complicity in the "Popish Plot" of 1678 to put the Roman Catholic James, duke of York (later James II), on the throne. He was born at Deddington in Oxfordshire, allegedly the son of a butcher, but probably the child of a prosperous grazier. Educated at Oxford University and at Gray's Inn, he fought briefly for Charles I early in the Civil War. Called to the bar in 1653, he practised during the Protectorate. A man of broad wit and fond of good living, he found favour with Charles II, was knighted in 1665, and was made a judge of the Common Pleas in June 1676. He became chief justice of the King's Bench in May 1678.

Presiding over the "Popish Plot" trials, Scroggs completely trusted the revelations of Titus Oates (*q.v.*) and welcomed the verdicts of guilty on the accused Roman Catholics. Although he harried them with execration of their faith, he did not infringe the rules of evidence. In July 1679 he dismissed the flimsy case against Sir George Wakeman, Queen Catherine's physician. In subsequent trials he convicted more "plotters," but his acquittal of Wakeman (and, by implication, of the queen) led to charges that Scroggs had been bribed by the court. He was deluged with public abuse; only the House of Lords and a grateful king shielded him from impeachment by the House of Commons in January 1681. His unpopularity forced Charles to remove him from the bench in April 1681 with a handsome pension. Scroggs died in London on Oct. 25, 1683.

Scroggs has been posthumously condemned by those who accepted contemporary Whig propaganda, but his worst excesses were committed on behalf of the Whigs. Although he displayed great passion on the bench, legal historians have found nothing incorrect in his application of the existing harsh law of treason.

See F. S. Ronalds, *The Attempted Whig Revolution of 1678–1681* (1937); A. Havighurst, "The Judiciary and Politics in the Reign of Charles II," *Law Quarterly Review*, vol. lxvi (1950). (H. G. Ro.)

SCROPE (originally THOMSON), **GEORGE JULIUS POULETT** (1797–1876), English geologist and political economist, best known for his study of volcanoes, was born in London on March 10, 1797, the second son of John Poulett Thomson. He assumed the surname of Scrope on his marriage in 1821 to the daughter of William Scrope. Educated at Harrow and St. John's college, Cambridge, he visited Naples, Italy, as an undergraduate in 1816–17, where his interest in volcanoes was stimulated by the actions of Vesuvius. In 1821 he examined the extinct volcanoes of the Auvergne and collected material for his work *On the Geology and Extinct Volcanoes of Central France* which he published in 1827.

Scrope commenced his researches at a time when the doctrines of Abraham Gottlob Werner (*q.v.*) were still in the ascendant, but his studies were soon to play a part in their overthrow. His first work, *Considerations on Volcanoes* (1825), is to be regarded as the earliest systematic treatise on volcanology, being the first attempt to frame a satisfactory theory of volcanic action and to show the part volcanoes have played in the earth's history. He early appreciated the important part played by water in igneous action and he effectively disposed of the elevation theory of craters.

In his work in the Auvergne he demonstrated the volcanic origin of the basalts and the formation of the valleys of the region by river action. He was elected a fellow of the Royal society in 1826.

Soon after his marriage, Scrope settled at the family seat of Castle Combe, Wiltshire, eventually devoting his attention largely to social and political questions. He was a member of parliament from 1833 until 1868 and published a long series of pamphlets and reviews advocating free trade and social reforms, especially with regards to the poor law. Scrope died at Fairlawn, near Cobham, Surrey, on Jan. 19, 1876. (C. E. T.)

SCROPHULARIACEAE, the figwort or snapdragon family of flowering plants, containing about 250 genera and 5,000 species, found on all continents (except Antarctica) but most numerous in temperate areas. The family is especially well represented in western North America, where more than 300 species occur in California alone, and in South Africa, from which about 780 species are known. Many members of the family are cultivated for their showy blooms, which in their diversity of size, colour and form rival those of the orchids. These ornamentals, representing about 65 genera, include snapdragon (*q.v.; Antirrhinum*), foxglove (*q.v.; Digitalis*), slipperflower (*Calceolaria; q.v.*), princess tree (*Paulownia*), speedwell (*Veronica*), mask-flower (*Alonsoa*), coral plant (*Russelia*), beardtongue (*Penstemon*), *Hebe, Linaria, Angelonia* and *Torenia*. Few additional Scrophulariaceae are of economic importance. The drug digitalis (*q.v.*) is the dried leaf of the common foxglove (*Digitalis purpurea*). Some members of the family are troublesome weeds, especially butter-and-eggs (*Linaria vulgaris*), mullein (*q.v.; Verbascum*) and several speedwells (*Veronica*). Witchweeds (*q.v.; Striga*) are serious parasites of various crops, mostly grasses, in warmer parts of the old world; *S. asiatica* has become established in southeastern United States. The orange-yellow roots of *Escobedia grandiflora* are sold in Colombian markets for colouring food. *Paulownia tomentosa* (princess tree) is a timber tree in Japan. The common garden

FROM L. H. BAILEY, "MANUAL OF CULTIVATED PLANTS"; REPRODUCED BY PERMISSION OF THE MACMILLAN CO.

SOME SPECIAL CHARACTERISTICS OF THE FAMILY SCROPHULARIACEAE

snapdragon (*Antirrhinum majus*) has been much used as an experimental plant in genetics.

Most Scrophulariaceae are annual, biennial or perennial herbaceous plants, but many, especially in warmer regions, are shrubs. Among the few trees are *Halleria lucida* of eastern and southern Africa, growing 45 ft. tall and 10 in. in diameter, and *Hebe parviflora* of New Zealand, about 25 ft. tall and 2 ft. in diameter. Many members of the family are parasitic, attaching themselves to the roots of other plants by means of suckers. Some, such as Indian paintbrush (*Castilleja*), witchweed (*Striga*) and eyebright (*Euphrasia*), are partial parasites that contain chlorophyll and thus can produce their own food through photosynthesis, although drawing water and minerals from the host. Others (*Harveya, Hyobanche*), lacking chlorophyll, are total parasites. Leaves of Scrophulariaceae may be alternate, opposite or rarely whorled on the stem and are smooth-edged to deeply toothed or lobed, or, in some aquatic species, divided into threadlike segments. *Hebe* has evergreen leaves. Many Scrophulariaceae produce numerous small seeds: in a capsule of hedge hyssop (*Gratiola virginiana*) nearly 1,800 seeds may be developed, and a single monkey flower plant (*Mimulus ringens*) can bear 300,000 seeds. In contrast, *Lagotis, Tozzia* and some New Zealand *Euphrasia* produce a single seed in each cell of the fruit. Seeds of Scrophulariaceae may be winged, almost smooth, reticulate, tuberculate, ridged, etc., and are spread mainly by wind. Some genera (*e.g., Scoparia, Penstemon*), produce seeds that may be ingested by animals and expelled later, growing from the droppings; those of certain species of *Veronica* and *Melampyrum*, which develop an oil-secreting gland, are dispersed by ants that feed on the oil; and seeds of aquatic and marsh species (*e.g., Gratiola, Limosella*) may be carried in water or in mud adhering to birds and mammals.

Flowers of Scrophulariaceae are borne singly along the stem or are grouped into clusters. The often two-lipped corolla consists of five united petals, with the upper two sometimes fused to appear as one (*Veronica*). The corolla lobes are similar to strongly dissimilar. The united portion of the petals (tube) is very short (*Veronica*) to long and either flaring (*Digitalis*) or narrow (*Buchnera*), reaching a length of six inches in *Escobedia guatemalensis*, the species having the largest flowers in the family. The four or five sepals are separate to almost fully united. The stamens are usually four, but sometimes two (*Veronica*) or rarely five (*Capraria*, some *Verbascum*). The ovary is two-celled, superior and with axile placentae. Most members of the family are pollinated by bees and flies; some species, however, are adapted for pollination by hovering moths (*Harveya, Penstemon albidus*), by butterflies (*Buchnera, Sophronanthe*) or by hummingbirds (*Castilleja, Macranthera*). Nearly all Scrophulariaceae have a capsular fruit, but in *Halleria, Teedia* and *Leucocarpus* the fruit is a berry and in the South African tribe Selagineae the fruit is a schizocarp.

The largest genera of the family are *Calceolaria, Pedicularis* (louseworts), *Verbascum, Veronica* and *Penstemon*. A few fossils (*e.g., Paulownia*-like leaves) have been attributed—for the most part doubtfully—to the family.

Certain closely related families, especially the broomrape family (Orobanchaceae), are sometimes included in the Scrophulariaceae. The genus *Paulownia* is often referred to the trumpet vine family, combining as it does the arboreal habit of the Bignoniaceae with seed characters of the Scrophulariaceae.

See F. W. Pennell, "The Scrophulariaceae of Eastern Temperate North America," *Academy of Natural Sciences of Philadelphia, Monographs no. 1* (1935).

(J. W. Tr.)

SCRUBBIRD, the name applied to two species of *Atrichornis*, an Australian genus of primitive perching birds that comprises the family Atrichornithidae. The noisy scrubbird (*A. clamosa*), of western and southwestern Australia, the male of which is noisy and imitative of other birds, is brown above, each feather barred with a darker shade. The throat and belly are reddish-white and there is a black patch on the throat; the flanks are brown. This species, which inhabits the thickest scrub of brambles and dense undergrowth, is in danger of becoming extinct. The rufous scrubbird (*A. rufescens*), from the forests of New South Wales, is dark brown except for an orange-brown tinge to the underparts.

SCUDÉRY, GEORGES (1601–1667) and **MADELEINE** (1607–1701) **DE,** brother and sister, established themselves in Paris as writers and critics. Both were born at Le Havre: Georges on Aug. 22, 1601, and Madeleine on Nov. 15, 1607. Georges settled in Paris in 1630, having abandoned his military career to turn to poetry and drama. When Madeleine joined him in 1638, he had already made a name for himself as a bitter protagonist in the quarrel of *Le Cid* (*see* Corneille, Pierre). He wrote a letter to the Académie Française criticizing the new play, and his own tragicomedy, *L'Amour tyrannique* (1638), was patronized by Richelieu in opposition to Corneille. Because of her brother's literary reputation, Madeleine was at once admitted to the Rambouillet coterie, the leading Parisian salon of the day, where she met almost all the more noteworthy figures in contemporary French society and literature. (*See* Rambouillet, Cathérine de Vivonne, Marquise de.)

Before long Madeleine was producing works of her own; her lengthy heroic romances, such as *Ibrahim, ou l'illustre Bassa* (4 vol., 1641), *Artamène, ou le Grand Cyrus* (10 vol., 1649–53), *Clélie* (10 vol., 1654–60), were soon the delight of all Europe. They appeared under the name of her brother, who almost certainly collaborated in them. He may have done little more than read the proofs; on the other hand, it is likely that *Almahide, ou l'esclave reine* (8 vol., 1660–63) was written by him. The two Scudérys certainly spent most of their lives together. When, in 1644, Georges went to Marseilles for three years, as governor of the fortress Notre-Dame-de-la-Garde, his sister accompanied him. In Paris they shared the same address until 1654, when Georges' political opinions as a Frondeur caused his banishment from the capital.

Meanwhile the name of Paul Pellisson, the brilliant man of letters, was being increasingly associated with that of Mlle de Scudéry. She met him in 1652 and formed with him a close and passionate friendship terminated only by his death in 1693. At about the same time she established her own salon, the *Société du Samedi*, which soon became a well-known hive of *préciosité*.

Although Georges was an industrious and prolific writer, only *L'Amour tyrannique* and an epic, *Alaric* (1654), have survived. He was elected to the Académie in 1650 and was always a prominent figure in Paris; but it is his sister who has kept the name of Scudéry alive. Her novels are landmarks in the history of the French novel. Although they have classical or Oriental personages as heroes and heroines, their language and action reflect the fashionable ideas of the time. Several of her contemporaries can be identified in these *romans à clef*. In *Clélie*, Herminius represents Pellisson; Scaurus and Lyriane are Paul Scarron and his wife (later Mme de Maintenon); and in the description of Sappho in volume X of *Le Grand Cyrus* the author paints herself, whence her pseudonym "Sapho." It is in *Clélie* that the famous *Carte de Tendre* appears, a sort of "Map of Love's Land," in which the river of Inclination waters the villages of *Billet Doux, Petits Soins,* and so forth. This literary amusement offers an excellent example of the *esprit précieux*. The novels are full of psychological observation, and reveal the author as a mistress of dialogue. Everything she wrote was in the most decorous spirit, which contrasts rather strongly with the general arrogance of her brother.

After six years in Normandy, Georges returned to the capital, where he died on May 14, 1667. Madeleine spent her later years publishing numerous volumes of conversations. She died in Paris on June 2, 1701.

Bibliography.—H. C. Lancaster, *French Dramatic Literature in the 17th Century*, part II (1932); C. Aragonnès, *M. de Scudéry, reine du Tendre* (1934); D. McDougall, *M. de Scudéry; Her Romantic Life and Death* (1938); G. Mongrédien, *M. de Scudéry et son salon* (1946).

SCULLING: *see* Rowing.

SCULPTURE may be broadly defined as the art of representing observed or imagined objects in solid materials and in three dimensions. There are two general types: statuary, in which figures are shown in the round, and relief, in which figures project from a ground; for a further discussion of the distinction *see* Relief. Sculpture is one of the oldest and most widespread

of the arts. It is also one of the most difficult, for it requires physical labour, patience and complete control of the materials involved for a long period of time.

One approach to the subject is that of techniques and materials. For a general discussion of the methods by which pieces of sculpture are created, *see* SCULPTURE TECHNIQUES. The specific technical requirements and possibilities of the various materials are discussed in greater detail in such articles as IVORY CARVING; JADE AND OTHER HARD STONE CARVINGS; TERRA COTTA; WAX FIGURES; and WOOD CARVING. Most of these articles also give a brief historical summary of sculpture in the material under discussion.

Another approach is historical, tracing the development of sculpture in a country or in a civilization. In regard to the sculpture of the far east, for example, there are separate entries on CHINESE SCULPTURE and JAPANESE SCULPTURE; Indian sculpture is discussed in the article INDIAN ART (which also covers the art of Ceylon); the sculpture of the Indonesian archipelago is treated in INDONESIAN ARCHAEOLOGY AND ART. In the middle east, where Islam is in general unsympathetic to sculpture, little of it exists; *see* ISLAMIC ART. The sculpture of the civilizations of the ancient middle east is of archaeological as well as artistic interest and is discussed in the articles on the civilizations. *See*, for example, EGYPT: *Ancient Civilization and Culture: Arts and Crafts;* BABYLONIA AND ASSYRIA: *Art and Art Objects*. For the Minoan civilization of Crete *see* CRETE: *Archaeology: Sculpture and Modeling; see* also AEGEAN CIVILIZATION. For primitive sculpture *see* PRIMITIVE ART.

Greek sculpture forms a major part of the subject matter of the article GREEK ART; Roman sculpture is likewise discussed in ROMAN ART. This article is devoted to the sculpture of western civilization after the classical period and is divided into the following main sections:

See also biographies of sculptors discussed in the text, and articles on the art of various periods: BAROQUE ART; RENAISSANCE ART; MODERN ART; etc.; *see* also references under "Sculpture" in the Index. (X.)

I. ROMANESQUE SCULPTURE

With the dissolution of the Roman empire in the west, cultural hegemony over the Christian world passed to the Eastern empire, with its centre at the court in Byzantium (Constantinople, now Istanbul). Byzantine art, in contrast to Greek art (which as it developed became increasingly naturalistic), endeavoured to transfigure the forms of physical nature into something supernatural and transcendental, and it evolved styles of elaborate flatness, skilfully repudiating the material and the corporeal, which suggested the absolute dominion of the spiritual. As a result the art of statuary, an art of material mass, almost ceased to exist; sculpture was limited to ivory carving and goldsmith work.

In the west sculpture was generally less suspect. From the beginning the Christian Church marked the graves of apostles and martyrs with stone or bronze memorials. The character of these did not at first differ from other contemporary memorials except by the occasional use of Christian symbols. The vast number of sarcophagi in Rome, executed for the most part after the reign of Constantine I, illustrate the development of this Hellenistic art, in which classic forms and drapery, not without dignity and grace, are united intricately with the conventional decorative motives of orientalized Antioch or the genre detail of Alexandria. After the 5th century they share the technical decadence of Rome. *See* also EARLY CHRISTIAN ART.

The revival of the arts under Justinian I found a wide expression in intimate sculpture such as ivory carvings and architectural ornament. There was a sporadic appearance of monumental relief sculpture, such as that on the Anglo-Saxon crosses of England. During the Carolingian renaissance of the 9th century there was even a revival of statuary, although none of it has survived. A truly sculptural instinct distinguishes the relief scenes of the great bronze doors on the cathedral of Hildesheim in Germany (early 11th century), where the lively figures are isolated in clear, frieze-like compositions and emerge three-dimensionally, with their heads almost in the round; the vigour and virility of this exuberant masterpiece contrast strikingly with the sophistication of Byzantine art.

The bronze Easter column set up, supposedly by St. Bernward, in Hildesheim early in the 11th century, is a modest prophecy of the monumental spirit which would distinguish the sculptural decoration of the new monastic buildings rising in much of western Europe. Developed in the abbey doorways and on the pillars and capitals of cloisters, where the sculptor had to learn anew the technique of stone carving and of rendering the human figure, this spirit gradually entered once more the art of the occident.

During the 11th century more and more churches were constructed in the Romanesque style, the massive forms of which are another indication of this sculptural instinct. Romanesque sculpture culminated in France in the great semicircular relief compositions over church portals, called tympanums. The example at Moissac, which represents the Apocalyptic vision with the 24 elders, is a particularly brilliant demonstration of how devices of style can so transform the objects of nature that they seem entirely purged of terrestriality. All the forms are suspended in a predominating plane that denies physical space. Differences in scale are masterfully exploited: the tiny figures of the elders are a foil to the looming image in the centre. With great consistency, every detail has been subjected to a process of stylization that produces rhythmic patterns in the drapery, hair and feathers. The central figure is so flattened as to appear disembodied, while the two towering angels have been so attenuated that their bodies have lost all mass.

The astonishing variety which these master sculptors achieved within the confining principles of Romanesque style can be illustrated on the one hand by the tympanum of Burgundy, such as the spectral "Last Judgment" at Autun or the "Pentecost" at Vézelay, and, on the other, by the less visionary sculpture of Provence, such as that of St. Trophime in Arles or of the church in St. Gilles, which retain many of the forms and characteristics of classical antiquity. (*See* also ROMANESQUE ARCHITECTURE.)

Another sculptural form that reappeared in Europe during the latter part of the Romanesque period was sepulchral sculpture, in which a sculptured figure of the deceased was cut or molded on top of a sarcophagus or on the sepulchral slab set into the floor of an abbey or cloister. *See* SCULPTURE, SEPULCHRAL.

II. GOTHIC SCULPTURE

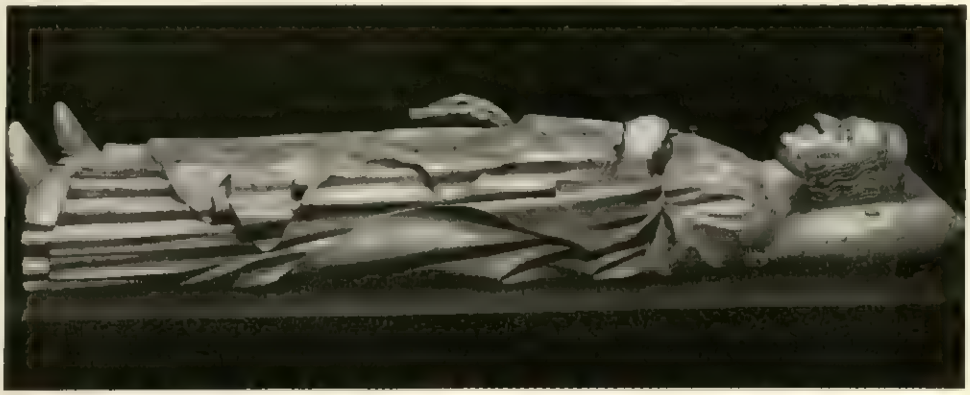
1. The Development of the Gothic Style.—The masterpieces of the rather forbidding art of the Romanesque, which is so intransigent in its rejection of earthly things, are in fact to be

The Apocalyptic vision with the twenty-four elders, tympanum of the church of St. Pierre, Moissac, France; *c.* 1135

Statue of Christ (Le Beau Dieu), south portal of Chartres cathedral, France; *c.* 1210–50

ROMANESQUE AND GOTHIC SCULPTURE

Gilded statue of the Virgin Mary (La Vierge Dorée), south transept portal of Amiens cathedral, France; 13th century



The tomb of Charles V in the abbey of St. Denis, France, by Andre Beauneveu; 14th century

Detail showing three prophets (Jeremiah, Simeon and St. John the Baptist), north portal of Chartres cathedral, France; 14th century

The Virgin Mary (Nuestra Señora la Blanca), portal of the west transept of León cathedral, Spain; mid-13th century

found principally on monastic buildings. They were meant for men who had withdrawn from the world. In the dynamic 12th century, the burghers of the newly powerful towns replaced the monks as the principal patrons of art, and it is to them, as lay Christians active in the world of affairs, that the art of the Gothic was increasingly addressed. The Christ of the west portal of Chartres cathedral was made soon after the radically dematerialized God of Vézelay, but by comparison seems more to partake of the substance of the physical world.

Likewise, by contrast with Romanesque art, the "Golden Virgin" of Amiens seems a credible creature of our physical world: the massive draperies and rounded upper portions impart a real bulk to her figure; she turns with a smile to a Child, who returns her affectionate gaze and whose orb seems a toy. Yet a brief comparison with any draped figure of classical antiquity will disclose how profoundly medieval this Gothic figure is, with the parts of the body completely obscured and the drapery composition not really hanging but swinging upward toward the spiritual focus of the work—in this instance, to the relation of Mother and Child, but more characteristically to the masklike faces with their great, hypnotic eyes that suggest the mystic state of the visionary. Never can the position of the legs be clearly determined under the draperies of Gothic statues; nor is there any sense of the interaction of weight and support in an organic structure, even when religious considerations demand the exposure of the body. The Gothic sculptor no longer rejects the physical world, but he selectively readmits only what he can exploit in the interests of spiritual expression.

Gothic art embodies the popular religious fervour that gained momentum all through the 12th century and culminated in the 13th, an age of wide-ranging spiritual enthusiasm and holy heroes—St. Francis of Assisi, St. Dominic, St. Thomas Aquinas and St. Louis, king of France. Huge sculpture shops were developed about the great cathedrals, Chartres, Paris, Bourges, Reims, Amiens and all the rest, and there the sculptors of all Europe were trained. The later Gothic sculpture of Bamberg in Germany, for example, traces its ancestry to the style of Reims during the previous generation; eventually the French style permeated almost the whole of Europe. Occasionally a genius of truly impressive individuality emerged, such as the master who produced the tragic reliefs on the rood screen, the Crucifixion group and the statues of benefactors for the cathedral of Naumburg in Saxony.

In the later 13th and in the 14th centuries the human and pathetic aspects of Gothic sculpture were intensified and its monumentality was often exchanged for intimacy, elegance and subtlety. Another important current, that of greater realism, emerged later in the 14th century; and in Burgundy, whence a new ascendant culture was soon to be diffused over much of Europe, this realistic tendency culminated in the work of the greatest sculptor of the end of the century, Claus Sluter. His masterpiece, the famous "Well of Moses" in Dijon, illustrates his capacity to endow the old Gothic forms with massive bulk and with trenchant realism in such details as the head, without compromising their fundamental medievalism. This style survived well into the later 15th century, producing such works as the tomb of Philippe Pot, now in the Louvre.

2. Tomb Sculpture.—The growth of naturalism in Gothic figure sculpture can be traced more continuously in tomb figures than in any other field. The tombs in the abbey of St. Denis, near Paris (1264), built by St. Louis for his ancestors and his sons, are characteristic examples of 13th-century tombs. In these the figure is modeled not in relief but in the round. Each figure, represented as in early manhood and rendered as a standing figure laid upon the ground, is graciously idealized. Each has a simple architectural framework, low in relief, and each is placed on a base embellished with pictorial reliefs. The expression is calm and benign and the draperies straight and simple with long clearly incised lines.

Characteristic of the 14th century is the tomb of Charles V at St. Denis by André Beauneveu, where the advancing realism of the century expressed itself in accurate portraiture and in more flowing and natural draperies. The figure is portrayed in the stiffness of death, and about him are grouped representations of his relatives in the costumes and attitudes of mourners. The fine tombs of the popes of Avignon—one of which is elaborated with a canopy—and the effigy of Robert d'Artois at St. Denis, clad in full armour with a lance in his hand, are other examples which illustrate the growing interest in actuality. This principle reached its widest acceptance in the 15th century. At Tournai, Belg., there was developed the type of tomb in which the figure of the deceased, no longer dead and recumbent, kneels before the Virgin or some religious object; these tombs, the production of which amounted to an industry, were exported to all parts of England, France and Germany and widely imitated. The monument to Isabelle de Bourbon in the cathedral at Antwerp (*c.* 1465) and the tomb of Louis de Male, at Lille (1455), both of which are of bronze, are characteristic examples of this art in which the elaboration of detail and the representation of action and of personality are clearly the preoccupation of the sculptor. Burgundy produced an equally realistic funerary art, of which the tomb of Philip the Bold (completed 1410), begun by Claus Sluter, is an elaborate example.

3. Italian Gothic.—During the later medieval centuries Italian sculptors turned repeatedly to the inevitable models of classical antiquity. The style of the monumental bronze doors which have survived in numerous examples also suggests the closer relations with the Byzantine east, although those in Pisa and Monreale by Bonanno of Pisa, and the famous ones in Benevento (12th century), are more vigorous and three-dimensional than Byzantine relief. The antiquarian tendency is especially pronounced in the 13th-century sculptures made at the instance of Frederick II, and particularly in those made for a triumphal arch erected at Capua, the extant fragments of which include toga-clad, laurel-crowned portrait busts and other allusions to the antique.

The artistic origins of Niccolò Pisano probably trace back to this southern school but he was active chiefly in Tuscany. His first work, the hexagonal pulpit completed in 1259 for the baptistery of Pisa, is the masterpiece of this antiquarian tendency, for there he breathed the Gothic spirit into the massive forms of antiquity and disposed them in unique relief compositions of which the teeming profusion is rigorously disciplined. In the famous herculean nude "Strength," his genius takes a form of classical antiquity and medievalizes it with a swinging Gothic compositional curve and with Gothic pathos. In his later works, the pulpit in Siena and the fountain of Perugia, he grew constantly more Gothic. His son, the prolific Giovanni Pisano, is the greatest of Italian Gothic sculptors. The range of his passionate dramatic art is seen in his masterpiece, the pulpit completed in 1301 for S. Andrea in Pistoia, with its masterfully exploited high relief and its profoundly emotive statuettes. The severer art of Arnolfo di Cambio retains more of the spirit of his master, Niccolò, as in the great canopy tombs (of Adrian V, in S. Francesco, Viterbo; of the cardinal de Braye, in S. Domenico, Orvieto), and especially in the heroic statues of the Virgin (Opera del Duomo, Florence) made for the façade, begun by Arnolfo but later destroyed, of the cathedral of Florence. Tino di Camaino amplified the sculptural enrichment of tomb composition into the splendid form of the monument for Cardinal Petroni (1318), in the cathedral of his native Siena, and endowed his figures with a reflective lyricism and a rhythmic linearity that recall the painting of that city.

Another masterpiece of the Sienese school is the extensive decoration of the cathedral of Orvieto, probably by Lorenzo Maitani; there the linear subtleties and aristocratic elegance of the school luxuriate in ornamental relief plans of great opulence, while the sharp, wiry forms of the bronze sculptures above uniquely exploit this exceptional medium by projecting boldly and piercingly from the architectural mass. In this medium of bronze, the masterpiece of the period is Andrea Pisano's famous south portal (1330–36) of the Florentine baptistery, the more severely linear figures of which are harmoniously arranged in simple, squarish compositions further clarified by gilding and by contrast with the complicated form of quatrefoil panels.

Later in the 14th century, in a spiritual reaction aggravated by the plagues which had decimated the population, there was a

tendency among both painters and sculptors to exchange the more progressive aspects of the art of their predecessors for a strangely unorthodox proliferation of forms, often less human and more formalized. This reactionary period is best represented by the great polychrome marble tabernacle (1355–59) in Or San Michele, Florence, by the leading painter and sculptor of the time, Andrea Orcagna. Other followers of the Pisano tradition carried it to northern Italy and expanded it under local and foreign influences, for example, in the virile and vigorous style seen in the rather menacing and Teutonic equestrian figures of the elaborate Scaliger tombs in Verona.

III. RENAISSANCE SCULPTURE

1. The Beginnings.—The radical innovations in Tuscan sculpture about 1400 are among the first signs of the Italian Renaissance. In the art of certain transitional figures, such as Jacopo della Quercia, the medieval suspicion of the body was dispelled and heroic nudes re-created the physical beauty of the antique in a spirit and style intelligible to the late medieval audience. One of the first monuments of the new age is Della Quercia's tomb of Ilaria del Carretto (*c.* 1406) in the cathedral of Lucca, in which the Burgundian free-standing tomb was translated into Latin, with richly sculptural figures of nude *putti* bearing garlands. The effigy partially retains the Gothic spirit, however, as in the drapery passages which conceal the lower parts of the body.

In the more progressive Florence, which for the next two centuries was to be the world centre of sculpture, much that is Gothic survived in the work of the less radical artists, such as Lorenzo Ghiberti, who won the famous competition for the north portal of the Florentine baptistery and there enriched, developed and refined the model of Andrea Pisano. The subject of the competition was the sacrifice of Isaac; Ghiberti's competition piece, in which the difficult quatrefoil form is brilliantly exploited for both narrative and aesthetic effect, represents Isaac as a bound naked youth, one of the first in a millennium to be endowed with both the physical beauty and the restrained pathos of the antique ideal. It can be compared with the less elegant but more urgently dramatic trial-piece of Filippo Brunelleschi, whose Isaac, a more boyish body studied carefully from nature, shows such acutely observed psychological effects as the way the toes have been bent and rigidly tensed with fear. Thus mankind and the physical world it inhabits are the great themes which were to be elevated to predominance in Renaissance art. Ghiberti's later east doors for the baptistery were said to be worthy of the Gates of Paradise, a sobriquet still in general use.

The sharpest break with the medieval past was made by Donatello. After several important early works, he was commissioned in 1411 to make a statue of St. Mark for Or San Michele. For this revolutionary statue Donatello restored to art a pose of ancient Greek sculpture, the weight mainly on one leg, with the hip over that leg higher and slightly advanced and the shoulder lower and slightly receding. The formula rationally and articulately expresses the interaction of weighing and supporting factors in the structure of the human body, and this statue, for the first time since classical antiquity, thus recognizes the inherent validity of man. It is, however, no mere imitation of the antique. The right arm and hand do not hang with the relaxed freedom usual in ancient sculpture but press with barely perceptible tension against the thigh, and two huge fingers toy nervously with a fold of drapery in the absent-minded, involuntary way they often do when one is under a strain. This, even more than the pathos of the furrowed brow, hints at the internal turmoil of a simple, solid and normally steady man in the grip of a tremendous experience which partakes of the divine: a conflict of external tranquility and internal tension that is wholly unclassic. This imaginative re-creation of a real personality, in all its physical, psychological and spiritual complexity, was to become the distinguishing achievement of modern western art, but in 1411 it was quite unprecedented.

At the same time, "St. Mark" is placed on an unyielding and thoroughly improbable pillow, an early foreshadowing of the almost perversely personal and ultimately inexplicable elements which constantly increase in Donatello's late work and which preclude what he must have felt as the rather complacent rationality of much antique art. The "St. George" and the "St. Louis," also made for Or San Michele, and the statues for the campanile constitute a series of constantly more profound variations on the theme of the "St. Mark." This art of characterization culminated in the astonishing achievement of the "Gattamelata," the first colossal bronze equestrian statue since antiquity, in which a mount that is effortless and masterly, in comparison to the less convincing antique prototype, is used not merely to suggest equestrian prowess but rather to enhance the majesty of a great man, the paragon of the spiritualized active life. A closer view, however, somewhat qualifies this eulogy; the head discloses many psychological facets—determination, calculation, suspicion, bitterness, introspection, even compassion—the reconciliation of many conflicting tendencies not all conventionally "good" but all marvelously human. This statue is the perfect embodiment of the Renaissance.

Donatello's bronze "David" is the first monumental nude statue since antiquity and, no less important, the first truly free-standing figure with a full range of multiple views, although the front predominates. The relief of Herod's feast in the Sienese baptistery (1423–27) is one of the earliest extant elaborated demonstrations of perspective, while other very low-relief compositions in marble (*stiacciato-rilievo*) showed how that translucent medium could be endowed with dramatic pictorial effects of atmosphere and movement. All this is only a general indication of Donatello's historical importance. In his last works, such as the pulpit reliefs in S. Lorenzo, Florence, he is the modern Christian visionary, whose individual mysticism is very unlike the institutional, collective mysticism of medieval art.

Luca della Robbia was the fourth great innovator of early Renaissance sculpture. His great marble singers' gallery for the Florentine cathedral and his many beautiful Madonna reliefs in a new medium, coloured and glazed terra cotta, restore the calm simplicity, clarity, harmony and balance of truly classic art in an unpretentious way closer to ordinary humanity than the more Olympian ideal of antiquity. His earlier work, redolent of optimism, expresses an affecting approbation of the Renaissance rediscovery of the world, a spirit that curiously recedes in the more abstract and ascetic style of his late works.

2. The 15th Century.—The innovations of these masters were refined and augmented by the less revolutionary stylists of the middle and later 15th century. Donatello's design for the tomb of the schismatic pope John XXIII in the Florentine baptistery (1425–27) exploits the great Corinthian columns of the architecture in converting a Gothic canopy tomb into a classic wall tomb composed of antique elements; this remained a model for the succeeding generations of Renaissance sculptors. Bernardo Rossellino gave it a less personal and more orthodox form in his tomb of the humanist Leonardo Bruni (*c.* 1445) in Sta. Croce, Florence. Desiderio da Settignano, a lyric and sensitive sculptor of exquisite virtuosity, made the tomb of Carlo Marsuppini (*c.* 1455) in the same church a richer and less somber elaboration of the same theme. Antonio Rossellino, Bernardo's younger brother, carried the form to the highly ornamental and pictorial extreme of the tomb of the cardinal of Portugal (1460s) in S. Miniato al Monte, Florence. The brilliant Antonio Pollaiuolo endowed his bronze nudes with an intensified animal vitality; they could remain the exhilaratingly unliteral hyperboles still permitted by the purely empirical, unsystematic anatomy of art before the reforms of Leonardo da Vinci. The work of the versatile Verrocchio ranges from a patrician charm and freshness in his lesser works to the rugged, monumental power of his great equestrian general, "Colleoni." The preoccupation with style and execution seen in the works of his contemporaries is well illustrated by his brilliant tomb of Pietro and Giovanni de' Medici (1472) in S. Lorenzo, where all reference to death is excluded from a work of pure artistic abstraction. Sepulchral art outside Florence is represented by the tomb of the doge Pietro Mocenigo (*c.* 1485) in SS. Giovanni e Paolo, Venice, by Pietro Lombardi.

In France, during the 15th century, a wholly native development

in late Gothic sculpture, called the *détente* ("relaxation"), is in some ways equivalent to the early Italian Renaissance, for the extreme realism and the intricate drapery compositions of the later Gothic were replaced by a sweet and simple idealism. At the end of the 15th century its leading exponent, Michel Colombe, actually appropriated some of the new Italian forms, as can be seen in his tomb of Francis II of Brittany in Nantes, but his refined sensitivity to feminine beauty is very French. In 15th-century Germany, however, the realism, the emotionalism and the tortuous complication of the draperies were carried by such masters as Veit Stoss to an extreme that has been termed the late Gothic baroque, although a calm lyricism akin to the *détente* tempers the carvings of Tilman Riemenschneider. The more massive and monumental style of Adam Kraft's reliefs of the stations of the cross in Nürnberg (1505) is another independent approximation of the early Renaissance. Peter Vischer, also of Nürnberg, knowingly and unslavishly synthesized the Italianate and the Germanic, but it was not until the second half of the 16th century that northern sculptors were at home in the new art imported from the south.

3. Leonardo da Vinci and Michelangelo.—The artists of the High Renaissance, after *c.* 1500, evolved a truly classic style, serene, lucid, harmonious and more monumental than the art of the 15th century. The tremendous intellect of Leonardo da Vinci so enlarged artists' understanding of physical man and the physical world that, although he was only incidentally occupied with sculpture and none of his works long survived him, all sculpture, from his own time down to the 20th-century revolutions of modern art, is indebted to him for his full realization of a complete and systematic mastery of human anatomy. This vastly enlarged the expressive scope and illusional conviction of representational figure sculpture. Now, drawing upon antique sources, a great master could fully express the High Renaissance ideal of man the beautiful, harmonious and noble as Andrea Sansovino, for example, did in the sculptures on the Sforza and Basso tombs in S. Maria del Popolo in Rome.

The potentialities of Leonardo's innovations reached their greatest fulfillment in Michelangelo. In his early Pietà in St. Peter's, Rome, a marble whose unrivaled technical perfection realized the promise of a number of the sculptor's brilliant youthful works, he imparted a mood of calm and tender elegy to the monumentality, the plasticity, the idealism and the harmonious repose seen in Andrea Sansovino's and all High Renaissance art. There is a great clarity and logic in the composition of two interlocked crescents, with draperies emphasizing the structurally and psychologically important point where the Madonna's hand supports but does not actually touch the dead body of her Son. This classic phase of Michelangelo led to the colossal marble "David" (1501–04), a splendid nude figure nearly 13½ ft. high, in which new complications began to subvert the clarity of the High Renaissance. The multiple views, in a way characteristic of classical sculpture, are compositionally subordinated to the main front view; but this is curiously at odds with the content, since one must then walk around to the right, to a very secondary view, in order to see in the face the theme of the whole work: the heroic defiance of David that blazes forth from his scornful glare. Moreover, the psychologically very particularized state of this head is in conflict, by classic standards, with its physically very generalized, wholly ideal form.

These dissonances erupted into a violent rejection of the classic style in Michelangelo's next statue, the "St. Matthew" in the Florentine academy, begun in 1506 and abandoned in a rough-hewn state that perpetuates the interrupted creative act. The traditional stance of Donatello's "St. Mark" is now wrenched into the violent pose called *contrapposto*, and in this case deliberately reversed (hip lower over the weight-bearing leg and shoulder higher), so that the device originally evolved to express repose now expresses its extreme antithesis, a terrible tension that locks the struggling figure in a painfully frustrated standstill. The motive attains to the stunning tragedy of the two nude slaves in the Louvre and of the later unfinished ones in the Florentine academy and expresses the torturing ambivalence Michelangelo felt toward the human body, which he called "the earthly prison of the soul." These works belonged to various projects for the tomb of Pope Julius II, which was originally intended as a vast monument of about 40 large statues, but, in the course of the 30 years intermittently devoted to it, was repeatedly reduced by the pope's heirs to the pitiful compromise now in S. Pietro in Vincoli, Rome.

The Medici tombs in the new sacristy of S. Lorenzo, Florence (1520–33), which were carried nearer completion, are part of an architectural ensemble by Michelangelo himself, who would also have executed the frescoes; there would have been bronze river gods below (his clay model is now in the academy) to balance the symbols of the times of day on the sarcophagi above. The Medici dukes seated above, whose idealized portraits are so generalized they represent mankind rather than individual men, are thus released by death from the prison of the body and from the bonds of time and place, and, turning toward their patron saints and the Madonna diagonally across the room, seek unity with God. Late in Michelangelo's life the terrible conflicts of these tragic works are at last resolved, as in the sublime Pietà now in the Florentine cathedral but originally intended for his own tomb by the nearly octogenarian Michelangelo, who carved his self-portrait in the Nicodemus tenderly releasing the dead Christ from his embrace. The wraithlike forms of the even more dematerialized "Pietà Rondanini" in Milan, a fragment from the very end of his nearly 90 years, testify that, as Michelangelo said in one of the poems of his old age, he had turned from ". . . painting and sculpture, to that Divine Love spreading arms wide from the Cross to embrace us."

4. Mannerism.—Even the classic calm, clarity and harmony of Michelangelo's early works, as the Vatican "Pietà," were permeated with a profound melancholy that sets them apart from a characteristically optimistic artist of the High Renaissance like Raphael. Twenty years later the spirit of that fortunate but brief period seems to have soured, and there was a deliberate reversal of all of the qualities that had been cultivated in its art. One of Michelangelo's least typical works, the "Victory" group originally intended for the tomb of Julius, is a good introduction to the new movement, which is now neutrally termed Mannerism. The great attenuation of forms, the unreal pose, the wide-eyed, fixed stare that has no object and the precariously towering verticality of the composition combine to produce a strange and disconcerting air of enigma and irrationality which is the negation of classic art and has therefore been called anticlassicism. These qualities were carried to an extreme in the typical work of the time, the "Madonna and Child With St. Anne" (1525) in Or San Michele, Florence, by Francesco da Sangallo, whose tomb sculptures, among the most impressive monuments in the style, add a sinister realism to all the other expressionistic singularities of anticlassical Mannerism. Although the greatest sculptor of the generation, Alonso Berruguete, was trained in Florence and Rome, he returned to his native Spain and there produced such masterpieces as the polychrome sculptures now in the Valladolid museum, audaciously twisted and flamelike figures of great expressive power; or the remarkable alabaster Transfiguration group placed high over the choir screen of Toledo cathedral, where the translucent material in which this turbulent composition is carved is set aglow by the light of the great rose window.

Artists of more moderate temperament avoided these extremes. Jacopo Sansovino developed the objective classic ideal of his master, Andrea, into the subjective aestheticism seen in the "Apollo" on his Loggetta in Venice. Its elegantly lifted shoulder converts what was now felt as the merely physical logic of a traditional pose into a hyperbole of grace that accords with the extreme ideal of the refined, masklike face, huge eyes and tiny mouth, with the smooth, abstract surfaces and with the sweeping, continuous curves of the contour lines. The style of this statue foreshadows the reaction, toward the middle of the 16th century, against the violence and pessimism of the current style. Benvenuto Cellini's "Perseus," and especially its fantastic base adorned with elegant and hypersensitive figures, may well be the masterpiece of this phase of Mannerism, in which the fidelity to exclusively private ideals of beauty is often carried to an esoteric extreme. This extreme is considerably modified by reference to nature and to

classical antiquity in the work of Giovanni da Bologna, who, in his earlier compositions, addressed himself to the problem of multiple views and brilliantly solved it in the famous "Sabine" group by choosing a turning action that reasonably generates a spiral composition and thus impels a continuity around the statue, the full effect of which can be perceived only in motion.

In France the Renaissance created many decorated tombs of great beauty, among which those of Cardinal Amboise in Rouen cathedral and of Francis I at St. Denis by Pierre Bontemps are perhaps the most celebrated. Jean Goujon, one of France's greatest sculptors, worked at the time; an example of his vital and gracious style is the "Fontaine des Innocents" in Paris. The French sculptor Germain Pilon moderated the extreme Mannerism of Goujon and his contemporaries with greater naturalism, and, in a way characteristic of his generation and of the new age of the Counter-Reformation, returned with impressive results to the religious themes that had little occupied the sculptors of the mid-century. His effigy of René Birague in the Louvre is a perfect balance between sympathetic naturalism and monumental restraint. The splendid "Tombs at Brou" (1505–26) near Bourg, built for Margaret of Austria by Konrad Meit of Worms, are characteristic of the ornate, lingering Gothicism of the Renaissance in Germany.

IV. BAROQUE SCULPTURE

1. The Beginnings; Bernini.—A precocious example of the 17th-century rejection of Mannerism is seen in Francesco Mochi's brilliant Farnese equestrian monuments in Piacenza (1612–29), where the forms are pierced and opened up and the momentary, unstable poses, with draperies fluttering and tails lashing, give a vivid movement that releases the figures from the Mannerist spell. Their naturalism and pictorialism are also hallmarks of the coming baroque. No field was more congenial to the spirit of baroque art than sculpture carried out on a conspicuous scale. The baroque artist achieved dramatic pictorial unity by abolishing the traditional limits separating painting, sculpture and architecture. The solid masses of sculpture and even of architecture were made to move in space by means of such motive forms as undulations; sculpture was transformed by such painter's devices as richly varied illusionistic textures, coloured materials and irregularly dappling light effects.

Giovanni Lorenzo Bernini, the greatest sculptor of the 17th and 18th centuries, amplified the style in marble, establishing the sculptural principles for those two centuries in a series of youthful works of unrivaled virtuosity, as the "Apollo and Daphne." Stone was now completely emancipated from stoniness by open form and by an astonishing illusion of flesh, hair, cloth and other textures, pictorial effects that had earlier been attempted only in painting. These qualities make what his contemporaries called his "speaking portraits" seem unprecedentedly alive; portrait sculpture for two centuries is a variation of these innovations. In the statue of St. Longinus in St. Peter's in Rome, Bernini created the characteristic formula of baroque sculpture by throwing the draperies into a violent turmoil, the complicated and broken involutions of which are not rationally explained by the figure's real bodily movement but seem paroxysmally informed by the miracle itself. The famous group of the miraculous vision of St. Theresa in the Cornaro chapel of Sta. Maria della Vittoria, Rome, is the masterpiece of baroque religious sculpture, and shows how Bernini's intellect could organize the arts of architecture, painting and sculpture in an overwhelming assault on the senses that dispels the resistance of the intellect. This ambitious plan is typical of the mature Bernini, whose spiritual and artistic aspirations now exceeded the scope of his early secular salon statues. His later works were largely religious and unprecedentedly vast in scale, as the dazzling "Cathedra Petri" which covers the whole end of St. Peter's in Rome with teeming multitudes of figures.

The tombs of Bernini are magnificent spectacles in which symbolic figures, clothed in sweeping draperies, with rhetorical gesture and expressive features, share in some emotional experience, theatrically depicted. An example is the tomb of Alexander VII in St. Peter's, Rome. The pontiff, set in a great apse, kneels on a high pedestal about which Charity, Truth, Justice and Wisdom weep disconsolately while Death, a skeleton, raises the great draperies of polychrome and gold that veil a darkened doorway. The fountain of the Triton in the Piazza Barberini, Rome, from which all clarity of profile or of shadow, all definiteness of plane, are removed, is also characteristic of Bernini's style, widely imitated throughout Europe.

Bernini's art was the basis of all baroque sculpture, but his extreme was moderated by his more conservative contemporaries, such as Alessandro Algardi (relief of "St. Leo and Attila the Hun," 1646, St. Peter's, Rome) and especially the Fleming François Duquesnoy. The latter's "St. Susanna" in the Sta. Maria di Loreto in Rome, a figure after the antique but enlivened with Berninian textures, was originally made to look toward the observer and, with a gesture, to direct his attention to the altar. The distinction between art and life which the Mannerists had cultivated is banished by this active participation of the statue in our space and our activities, another important innovation of Bernini and his followers.

2. Other Baroque Sculpture.—Duquesnoy was much admired in France, where the sculptors of Louis XIV, such as François Girardon, continued his tradition of setting correct and charming allusions to the antique in a pictorial and spatial context that is wholly baroque. Girardon's tomb of Richelieu, in the Church of the Sorbonne, Paris, is illustrative of the baroque monuments of France, calmer and more conservative than those of Italy. The dying cardinal, lying on his sarcophagus and originally gesturing in supplication toward the altar, is upheld by Religion and mourned by Science. The three figures, united by the lines of skilfully arranged draperies, are informed by a solemn and touching sentiment. The academic discipline imposed by the Sun King's ministers, especially Colbert, discouraged less tractable spirits, such as the passionate genius Pierre Puget, whose unique expressions of anguish are couched in the physical terms of highly original works like the Milo of Crotona; here the composition of a figure rigid with pain is jammed into a plane that expresses its helpless and tragic captivity, and the open form of the baroque is given the highly personal interpretation of a great gaping hole like a vortex.

Another of the sculptors of Louis XIV, Antoine Coysevox, had begun in the official "academic baroque" style, but his later works, undertaken after the death of Colbert, are witnesses of the gradual acceptance of the baroque in France, which now acquired the artistic leadership that Italy had long held over the rest of Europe. At the same time, the style was made lighter, gayer and more ornamental, in accordance with 18th-century taste, as seen in the famous "Horses of Marly" at the entrance to the Champs Élysées in Paris, by Guillaume I Coustou. Coustou's bust of his brother Nicolas has a characteristic freshness and informality whereby 18th-century artists avoided the grandeur they found pompous in the Berninian tradition.

The monument to the Great Elector in Berlin by Andreas Schlüter, a realistic and robust equestrian statue, is representative of the Berninian tradition in Germany, as is also the periwigged "Apotheosis of Prince Eugene" by Balthasar Permoser in the Barockmuseum of Vienna. The baroque in Germany attained at times astonishing vitality and elaboration of form; the Trinity column, in Vienna, is an example. In England the baroque spirit is less understood. Of the many baroque monuments in Westminster abbey, the best one, the tomb of Lady Elizabeth Nightingale, is by the Anglicized Frenchman Louis François Roubillac. The Pietà in Valladolid, by Gregorio Hernández, is characteristic of the more fervid devotional sentiment in Spain, embodied in polychrome images of vivid reality and clear formal simplicity that remain almost untouched by the style of Bernini.

3. Rococo.—This 18th-century style that reduced the baroque to exquisite refinement was the art of the aristocratic salon and boudoir. The little marble "Mercury" (1741) of Jean Baptiste Pigalle is almost wholly Berninian, except in its intimacy and deliberate unpretentiousness; even in Pigalle's most ambitious undertakings, as the tomb of the comte d'Harcourt in the Parisian cathedral, the relative scale of the figures is much reduced, the whole composition opened up, and an enacted tableau replaces the cere-

monious allegory of Bernini's tombs. At the same time, the more classical current of French sculpture continued and gained importance as the 18th century advanced. The clarified form and continuous, unbroken contours of Étienne Maurice Falconet's marble "Bather" (1757) adapt the classic tradition to a pretty and intimate rococo ideal that is the quintessence of 18th-century taste. This classicism was purified by Jean Antoine Houdon, who avoided the playful air of the rococo boudoir in his "Diana" (*c.* 1777) and his marble nude in the Metropolitan museum, New York (1782), His portraits, and especially his unrivaled busts of children, are the ultimate in the 18th-century refinement of Bernini's tradition.

V. THE 19TH CENTURY

1. Neoclassical Sculpture.—Houdon's younger contemporaries found his moderate classicism only a compromise and evolved a style so evocative of the antique that it is termed neoclassicism. This evocation does not mean imitation; Antonio Canova achieved a reflective, elegiac calm in images that allude nostalgically to the antique but that often form tableau compositions unprecedented in antiquity and still highly pictorial. The surfaces of such a masterpiece as his portrait of Pauline Bonaparte (completed in 1807) are smoothed into fluent abstractions, yet the fleshy and other pictorial textures of the baroque are not surrendered. His refined linearism, unknown in earlier sculpture, eulogizes feminine beauty in a mellifluously elaborated interplay of easy curves. His highly original composition in the Vatican "Perseus" boldly casts the figure in a swinging, continuous arc on a plane.

The tomb of Clement XIV by Canova, in the church of SS. Apostoli, Rome, commissioned in 1783 and unveiled four years later, is a good illustration of early neoclassicism. The theme is that of Bernini—the draped figure of the pontiff seated on his sarcophagus and mourned by Charity and Peace—but the dramatic action is replaced by a dreamy mournfulness, which is made impersonal by the generalized features, by classic draperies and by the definite geometry of the architectural forms. The tomb of Lord Nelson by John Flaxman, in St. Paul's, London, while remotely derived from Pigalle, shares the dignity and classic restraint of Canova, which became characteristic of all sepulchral art. The tomb of Queen Louise in Charlottenburg by Christian Rauch is one of the loveliest of these neoclassical tombs.

2. Realistic and Romantic Sculpture.—In the 19th century a new type of memorial, that of a statue placed in a public place, increasingly replaced sepulchral sculpture, and the neoclassicism that had dominated the first phases of 19th-century art was slowly modified by realism and romance. Pierre Jean David d'Angers, called upon to create in the streets of French cities many representations of famous Frenchmen, gave these not only a contemporary costume but also gestures and expressions in harmony with their characters and activities. His "Corneille" at Rouen, "General Drouot" at Nancy and "Thomas Jefferson" at Washington, D.C., are examples. His monument to the Grand Condé (1817–27) made a skilful compromise between official neoclassicism and the so-called troubadour style which the late rococo sculptors had evolved for monuments to personages of the distant past, but he imbued it with a fieriness that predicts the dashing cavalier of romanticism. François Rude richly developed this nationalization of French sculpture, as his statue of Marshal Ney in Paris demonstrates. He also did realistic subjects of everyday life, such as the Neapolitan fisherboy in the Louvre. His great relief on the Arc de Triomphe masterfully expresses movement and urgency in a composition which nevertheless maintains the formality appropriate to its architectural context; but the exciting gesticulation and the powerful, unidealized heads, especially of the screaming personification of France, were more strongly romantic in feeling.

Antoine Louis Barye's fluent modeling in clay conceived for casting in the dark bronze opposed neoclassical insistence upon white marble; but the meticulously detailed execution of his early works was surrendered in his maturity for broad modeling and monumental grandeur, as in the "Lion" of the Louvre. His increasing inclination toward sculptural rather than pictorial effects eventually led him to experiment with the stylizations of archaic Greek statuary, as in the fine group of "Theseus and the Minotaur," a work prophetic of the early 20th century. Another interesting sculptor among the romantics was the uneven Auguste Préault, whose astonishingly violent and enigmatic relief in the Chartres museum, called "The Carnage" (1834), prefigured Picasso's "Guernica."

The art of the clay modeler, as opposed to that of the stonecarver, was to have a long hegemony. In accordance with the romantic predilection for passionate and violent themes and for medieval subject matter, Jean Baptiste Carpeaux chose Dante's starving Ugolino for his major early work, but in his maturity he embodied the voluptuous gaiety of the second empire, as in his famous "The Dance" on the Paris opera house, where many of the devices of the baroque were adapted to modern taste. His spirited fountain in the Luxembourg gardens recaptured the pictorial warmth of French baroque masters. Far bolder and more fantastic modeling is seen in the statuettes the great lithographer Honoré Daumier made for himself, such as the "Ratapoil" or the relief, "The Emigrants," where the impetuosity of the modeling intensified the high emotional key of the tragedy and where the expressive distortions furnished modern sculpture with one of its most indispensable devices.

Auguste Rodin's highly naturalistic early work, "The Bronze Age" (1877), is effective because the banal studio pose of a man leaning on a staff produced an unconventional and expressive gesture when the staff was removed. From Daumier, Rodin had learned the bold modeling of surfaces that are emotive rather than literal; the statue is only a rough approximation that avoids the definitive finish of earlier sculpture and remains in a state of becoming. Eventually, Rodin even worked with mere fragments such as broken torsos, and he enormously enlarged the range of figure composition. The mass, hitherto the principal vehicle of sculptural composition, was explosively opened by these methods; instead of the interplay of solid and void of earlier sculpture, Rodin's works are fused with the surrounding space. These methods evolved in his many works, such as "Adam" (1880), "Eve" (1881) and others, originally conceived as a part of the masterpiece of modern sculpture, "The Gate of Hell," undertaken by Rodin in 1880 and never really completed. It was inevitable that the translucent nature of the marble surface should engage the attention of Rodin, and even though he always prepared the models in clay and left the execution in stone to assistants, such marbles as the "Kiss" (1885), when properly exhibited with light partly from the rear, appear to glow with the incandescence of their passionate intensity. (J. HUD.; J. HM.)

3. Late 19th- and Early 20th-Century Conservative Sculpture.—The work of Rodin is commonly regarded as marking the beginning of modern sculpture, which is discussed in a following section of this article. At the same time that the new movements were spreading from Paris throughout the western world, a strain of "conservative" sculpture continued.

Sometimes this was merely "official" sculpture. At other times it developed a considerable amount of grace and elegance. Conservative sculpture took its inspiration from nature but was a disciplined art. It represented persons and things, subject to selection and rejection, to composing and arranging, to considerations of place, material, appropriateness and so on; it was also influenced by great past examples, so that inevitably an element of eclecticism enters into this kind of work.

The conservative sculptors sought to avoid what is ugly (a matter of indifference to modern sculptors concerned with expression or "expressiveness" in various forms and not with beauty in the classical sense of the word), as well as all exaggeration of scale and affected "forcefulness." They had no desire to startle, to provide sensation or novelty. Their appeal was not to the nerves or to the tensions of modern life, and in this sense it may be said that they are "behind the times."

The general tendency for a sculptor of conservative leanings was to begin as either a neoclassicist or an imitator of the Renaissance and then in later life to make some slight concessions to the pressure of "modernism." A short summary of any contemporary or recent schools or individual artists almost always begins with

France, but precisely because France after the 1850s was in the forefront of modern movements, there is very little truly conservative sculpture to be found there. In fact it is in the United States that the conservative tendency has been most pronounced, just as the United States was the last to give up neoclassicism proper. Nevertheless, mention may be made of Paul Dubois, who was responsible for the tomb of General Lamoricière in the cathedral of Nantes (1878) and the statue of Jeanne d'Arc outside the cathedral of Reims (1896). He shows in all his works a deep feeling for the Renaissance. Louis Ernest Barrias has been admired for his commemorative statues and busts such as those of the duchesse d'Alençon (1904), the chemist Lavoisier (1898) or the young Mozart in bronze (1887). In England Sir Frederick Leighton worked in a belated neoclassic manner. In the U.S. Augustus Saint-Gaudens may be taken as the most distinguished exemplar of the conservative style. He was not perhaps as "native" as Daniel Chester French but he was typical of his time in being sensitive to French influence and international elegance, in much the same way that the architecture of the turn of the century was affected by study at the École des Beaux-Arts where Saint-Gaudens also worked. His subjects were American and many of them patriotic. Mention need be made only of the Robert Gould Shaw relief opposite the State House in Boston (1897) and the equestrian statue of Sherman (1903) at 59th street and Central park in New York. He also designed the fine new $20 gold piece of 1907 and the head on the $10 gold piece, the latter design originally projected for the figure of Nike-Eirene walking before General Sherman's horse. He is thus well known to numismatists and may be considered as an influence in saving U.S. coinage from a very nearly universal debasement of design in the 20th century. (A. K. McC.)

4. U.S. and Latin-American Sculpture to 1900.—Modern sculpture, like many other facets of modern civilization, is international in scope. Before turning to that subject, however, it will be useful to consider briefly the development of sculpture in the United States and in Latin America up to about 1900.

United States.—The United States can hardly be said to have a sculpture before the 19th century, although William Rush (1756–1833), a wood carver, has been called "the first native American to devote himself seriously and successfully to sculpture." In the middle years of the 19th century there came into prominence four sculptors: Horatio Greenough, who executed several government commissions in Washington, D.C.; Hiram Powers, known particularly for his portrait busts; Thomas Crawford, who did monumental sculpture; and William Wetmore Story, who lived and worked in Rome, where he was associated with several other prominent 19th-century Americans. Their contemporary, William Rimmer, was a teacher of Daniel Chester French; in the latter part of the 19th century John Rogers became well known for his small groups illustrating literary, historical and humorous subjects. Prominent conservative sculptors in the latter part of the century included Augustus Saint-Gaudens, discussed above; Paul Wayland Bartlett, who lived in France for many years and worked in the French romantic tradition; Frederick William MacMonnies, who also lived in France and is known for such sculpture as the Columbian fountain at the 1893 World's Columbian exposition in Chicago; and Daniel Chester French, sculptor of "The Minute Man" at Concord, Mass., the seated Lincoln in the Lincoln memorial in Washington, D.C., and other works with distinctively American subject matter. Lorado Taft is known for his monumental figures and also for his *History of American Sculpture* (1903; revised editions 1924 and 1930), the first comprehensive work on the subject.

Most of these men were well received in their time but with changing conditions in the 20th century have fallen in critical esteem. It has been suggested that of all U.S. sculptors who began their work before 1900, only two can be regarded as approaching greatness: George Grey Barnard, whose works include the colossal groups at the entrance to the Pennsylvania capitol buildings at Harrisburg, and Gutzon Borglum, known particularly for his colossal portrait sculptures such as the Mt. Rushmore memorial in South Dakota. (X.)

Latin America.—With the coming of Europeans to Central and South America, Indian symbolism and monumentality blended with Renaissance realism, baroque elegance and neoclassic refinement. Indian traits appeared in such European-introduced sculptural forms as the stone crosses that were erected in churchyards; statues, whether by European sculptors or aboriginal pupils, depicted Jesus, the Virgin Mary, saints and occasionally an earthly benefactor of the church. Materials were of wood, plant fibre pulp coated with canvas and gesso, or plaster. The statues often had real costumes and hair, glass eyes and teeth, and extremely realistic flesh, bloody, bruised and torn, with taut muscles and distended veins. Gold halos or crowns were added and costume textures were imitated by the gold-leaf-and-paint estofado technique. Many of these were undoubtedly inspired by paintings brought from Europe.

Few sculptors are known by name from the colonial period and fewer attributions are possible. At least a dozen can be identified in Mexico in the 16th century and twice that number in the 17th; the best known are José Cora of Puebla and his nephew Zacarías, and Gudiño of Querétaro. Many were both sculptors and architects, a necessity of the times. In the 18th century considerable artistic stimulus was provided by the Spanish-born neoclassicist Manuel Tolsa, first director of the academy in Mexico City, first to produce an equestrian statue in the new world (of Charles IV) and teacher of many sculptors of subsequent fame. The second most important artistic centre of the colonial era was Quito, Ecuador, which was known particularly for its decorative sculpture.

Following independence from Spain, sculptors in the new republics of Latin America, using techniques learned in Italy and France, produced hundreds of bronze and marble figures of such public heroes as Bolívar, San Martín and Morelos which adorn public squares in every city. In the late 19th and early 20th centuries, as ties with Spain were renewed, numerous monuments to Christopher Columbus were erected. The best-known single example of Latin-American monumental sculpture is undoubtedly the colossal bronze "Christ of the Andes" by Mateo Alonso of Argentina, erected in 1902 on the Argentina-Chile border to commemorate the peaceful settlement of a boundary dispute. For pre-Columbian sculpture *see* PRIMITIVE ART. (C. I. C.)

VI. MODERN SCULPTURE

1. Rodin's Immediate Successors.—Although the art of Rodin appears conservative in comparison to the painting of the time, in that he continued to use literary themes while painting did not, the new style that he evolved did much to revive sculpture's significance, and his importance to 20th-century sculpture can hardly be overestimated. His fresh search and revelation of the basic movements of modern life had a profound influence on sculptors who followed him.

Among Rodin's contemporaries another significant figure was Edgar Degas, whose sculpture, begun in the 1880s, was an intimate study of movement and light; in several respects it predicts 20th-century developments. Rodin's Italian counterpart, Medardo Rosso, lived in Paris during the 1880s; his work was known and owned by Rodin. Less gifted than Rodin, but interested in the same problems, Rosso used wax in such a way that light was suffused through sensitively modeled portraits and labile forms were created to express the flux that he felt was a condition of modern life. In Italy Russo influenced Arturo Martini and through him Giacomo Manzù, Marino Marini and Alberto Viani.

The ablest of Rodin's many pupils were Émile Antoine Bourdelle and Charles Despiau. Bourdelle's "Heracles" (1910) is an attempt to continue Rodin's active postures but the results are melodramatic and the forms are heavy and less sensitively modeled. Despiau, who was director of Rodin's shop from 1907 to 1914, also responded to the interest in classicism; his best work, "Girl From the Landes" (1904), was a balance of individual traits in the Rodin tradition, combined with graceful poses and well-rounded forms.

Two of the many other young sculptors attracted to Paris by Rodin's fame were Wilhelm Lehmbruck and Constantin Brancusi. Lehmbruck's early work has the soft modeling by touches of clay characteristic of the time, as in his "Mother and Child" (1907) and "Bust of a Woman" (1910). Brancusi's "Sleeping Muse"

(1906) and the small "Bust of a Boy With Head Inclined" (1907) reflect Rodin's later interests in the expressiveness of modeling as opposed to strenuous gesture. Pablo Picasso and Henri Matisse were also early disciples of Rodin, as was Jacob Epstein, particularly in his naturalistic and psychologically incisive portraits.

2. Avant-Garde Sculpture (1909–20).—In the second decade of the 20th century the tradition of body rendering extending from the Renaissance to Rodin was shattered and the Cubists, Brancusi and the Constructivists emerged as the most influential forces. Cubism (*q.v.*), with its compositions of imagined rather than observed forms and relationships, had a similarly marked influence.

One of the first examples of the revolutionary sculpture is Picasso's "Head of a Woman" (1909). The sculptor no longer relied upon traditional methods of sculpture or upon his sensory experience of the body; what was given to his outward senses of sight and touch was dominated by strong conceptualizing. The changed and forceful appearance of the head derives from the use of angular planar volumes joined in a new syntax independent of anatomy. In contrast to traditional portraiture, the eyes and mouth are less expressive than the forehead, cheeks, nose and hair area. Matisse's head of "Jeanette" (1910–11) also partakes of a personal reproportioning that gives a new vitality to the less mobile areas of the face. Likewise influenced by the Cubists' domination of their subject matter. Alexander Archipenko in his "Woman Combing Her Hair" (1915) explored the possibilities of concave areas of the body and replaced the solid head by its silhouette within which there is only space.

Brancusi also abandoned Rodin's rhetoric and reduced the body to its mystical inner core. His "Kiss" (1908), in which two blocklike figures share a powerful life gesture conveying the search for fulfillment, has a concentration of expression similar to primitive art but lacking its demonic power. In this and subsequent works Brancusi favored hard materials and surfaces as well as self-enclosed volumes that give to his subjects an introverted character. Brancusi was also the first artist to carve the bases of his sculptures to realize a poetic continuity, as in his bronze "Bird in Space" (1919), (the piece that became a *cause célèbre* in the 1920s when U.S. customs refused to admit it duty free as a work of art).

Raymond Duchamp-Villon began as a follower of Rodin, but his "Head of Baudelaire" (1911) contrasts with that by his predecessor in its more radical departure from the flesh; the somewhat squared-off head is molded by clear, hard volumes. His famous "Horse" (1914), a coiled springlike form bearing little resemblance to the animal itself, suggests in part the horsepower of locomotive drive shafts and conveys something of the mechanization of modern life. Duchamp-Villon may have been influenced by Umberto Boccioni, one of the major figures in the Italian Futurist movement and a sculptor who epitomized the Futurist love of force and energy deriving from the machine. In "Unique Forms of Continuity in Space" (1913) and "Head + House + Light" (1911) he carried out his theories that the sculptor should model objects as they interact with their environment, thus revealing the dynamic essence of reality.

Jacques Lipchitz came to Cubism later than Archipenko and Duchamp-Villon but after mastering its meaning he produced the best sculpture. In 1913, after several years of conservative training, he made a number of small bronzes experimenting with the compass curve and angular planes. They reveal an understanding of the Cubist reconstitution of the bodies in an impersonal quasi-geometric armature over which the artist had complete autonomy. Continuing to work in this fashion, he produced "Man With a Guitar" (1915), and "Standing Figure" (1915), in which voids are introduced, while in the early 1920s he developed freer forms more consistently based on curves.

Lehmbruck's mature style emerged in the "Kneeling Woman" (1911) and "Standing Youth" (1913), in which his gothicized, elongated bodies with their angular posturings and appearance of growth from the earth incarnate his belief in modern human heroism. In contrast to this spiritualized view is his "The Fallen" (1915–16), intended as a compassionate memorial for friends lost in the war.

3. Constructivism and Dada.—Between 1912 and 1914 there emerged an "antisculptural" movement, called Constructivism, which attacked the false seriousness and hollow moral ideals of academic art. The movement began with the relief fabrications of Vladimir Tatlin in 1913. The Constructivists and their sympathizers preferred industrially manufactured materials, such as plastics, iron and steel, to marble and bronze. Their sculptures were not formed by carving, modeling and casting but by twisting, cutting, welding, or, literally, construction: hence the name Constructivism.

Unlike traditional figural representation, the Constructivists' sculpture denied mass as a plastic element and volume as an expression of space; their compositions were often free transparent grids existing in space continuous with the spectator. In the machine, where the Futurists saw violence, the Constructivists saw beauty. Like their sculptures, it was something invented; it could be elegant, light or complex, and it demanded the ultimate in precision and calculation.

Seeking to clearly express "pure reality" with the veneer of accidental appearance stripped away, the Constructivists created imaginative objects totally devoid of sentiment or literary association; Naum Gabo's work frequently resembled mathematical models, and several Constructivist sculptures, such as those by Kazimir Malevich and Georges Vantongerloo, have the appearance of architectural models. The Constructivists created metaphors or equivalent structures of the new world of science, industry and production; many of the qualities of their sculpture appear in the furniture, architecture and typography of the Bauhaus (*q.v.*).

A second important offshoot of the Cubist collage was the fantastic object or Dadaist assemblage which, though tangent to Constructivism's iconoclasm, opposed its insistence upon rationality. Cubist collages were made from materials lying about in the studio, such as wood, cardboard, nails, wire and paper; examples are Kurt Schwitters' "Rubbish Construction" (1921) and Marcel Duchamp's "Disturbed Balance" (1918). This art generally exalted the accidental, the spontaneous and the impulsive, giving free play to associations. Its paroxysmal and negativist tenor led its subscribers into other directions but Dadaism formed the basis of the imaginative sculpture that emerged in the later 1920s.

4. Conservative Reaction (1920s).—In the 1920s modern art underwent a reaction comparable to the changes experienced by society as a whole. In the postwar search for security, permanence and order, the earlier insurgent art seemed to many to be antithetical to these ends and certain avant-garde artists radically changed their art and thought. Lipchitz' portraits of "Gertrude Stein" (1920) and "Berthe Lipchitz" (1922) return volume and features to the head, but not an intimacy of contact with the viewer. Tatlin and Aleksandr Rodchenko broke with the Constructivists around 1920. Jacob Epstein developed some of his finest naturalistic portraiture in this decade. Rudolph Belling converted from his mechanized "Head" to muscles and identity in his statue of "Max Schmeling" of 1929. Matisse's reclining nudes and the "Back" series of 1929 show less violently worked surfaces and more massive and obvious structuring.

Aristide Maillol continued refining his relaxed and uncomplicated women with their untroubled stolid surfaces; there was something hygienic about his figures that made the title "Bather" redundant. In Germany, Georg Kolbe's "Standing Man and Woman" of 1931 seems a prelude to the Nazi health cult, and the serene but vacuous figures of Arno Breker, Karl Albiker and Ernesto de Fiori were simply variations on a studio theme in praise of youth, body culture, vigilance and low blood pressure. In the United States adherents of the countermovement were William Zorach, Chaim Gross, José de Creeft, Adolph Block, Donald de Lue, Paul Manship and Wheeler Williams.

5. Sculpture of Fantasy (1920–45).—One trend of Surrealist or Fantasist sculpture of the late 1920s and the 1930s consisted of compositions made up of found objects, such as Meret Oppenheim's "Object, Fur Covered Cup" (1936). As with Dadaist fabrications, the unfamiliar conjunction of familiar objects in these assemblies was dictated by impulse and irrationality and could be

summarized by Isidore Ducasse's often-quoted statement, "Beautiful . . . as the chance meeting on a dissecting table of a sewing machine with an umbrella."

Of greater importance as art was the sculpture of a second group that included Alberto Giacometti, Jean Arp, Lipchitz, Henry Moore, Barbara Hepworth, Picasso, Julio González and Alexander Calder. Although these sculptors were sometimes in sympathy with Surrealist objectives, their aesthetic and intellectual concerns prohibited a more consistent attachment. Their art might best be called the sculpture of fantasy. Its sources were in visions, hallucinations, induced responses, reverie and memory, all realized in an intensely personal way. Giacometti's imaginatively derived "Palace at Four A.M." (1933), for example, contrasts with Bernini's "Ecstasy of St. Theresa" in that it does not interpret the artist's vision as if it had occurred in the exterior public world; Moore's series of "Forms" are partial inventions of shapes that interact on each other and space, suggesting life situations. The appeal of primitive and ancient ritual art to Moore, the element of surprise in children's toys for Calder, and the wellsprings of irrationality from which Arp and Giacometti drank were for these men the means by which wonder and the marvelous could be restored to sculpture. While their works are often violent transmutations of life, their objectives were peaceful, ". . . to inject into the vain and bestial world and its retinue, the machines, something peaceful and vegetative." ([Jean] Hans Arp, *On My Way*, Documents of Modern Art, vol. 6, p. 123, George Wittenborn, Inc., New York, 1948.)

6. Other Sculpture (1920–45).—The sculpture of Moore, Gaston Lachaise and Henri Laurens during the '20s and '30s includes mature, ripe human bodies, erogenic images showing an abnormal emphasis upon those parts of the body easily reached by the hands. These figures, reminiscent of Hindu sculpture, appear inflated with breath rather than supported by skeletal armatures. Lachaise's "Montagne" (1934–35) and Moore's several reclining nudes of the '30s are identifications with earth, growth, vital rhythm and silent power. Prior to Moore and the work of Archipenko, Boccioni and Lipchitz, space had been a negative element in figure sculpture; in Moore's "string sculptures" and Lipchitz' "transparencies" of the 1920s, it became a prime element of design.

Lipchitz' figure style of the late '20s and '30s is inseparable from his emerging optimistic humanism. His concern with subject matter began with the ecstatic "Joy of Life" (1927). Thereafter his seminal themes were of love and security and assertive passionate acts that throw off the inertia of his Cubist figures. In the "Return of the Prodigal Son" (1931), for example, strong, faceted curvilinear volumes weave a pattern of emotional and aesthetic accord between parent and child.

Among the sculptors of this period who dealt meaningfully with animal forms as well as the human figure was John B. Flannagan. His interest in what he called the "profound subterranean urges of the human spirit in the whole dynamic life process, birth, growth, decay and death" (quoted in Carl Zigrosser, *Catalog for the Exhibition of the Sculpture of John B. Flannagan*, p. 8, The Museum of Modern Art, New York, 1942) resulted in "Head of a Child" (1935), "New One" (1935), "Not Yet" (1940) and "The Triumph of the Egg" (1941).

Somewhat more mystical are Brancusi's "Beginning of the World" (1924), "Fish" (1928–30) and "The Seal" (1936). As with Flannagan, the recurrent egg form in Brancusi's art symbolizes the mystery of life. Nature in movement is the subject of Alexander Calder's mobiles, such as "Lobster Trap and Fish Tail" (1939) and others of leaves, trees and snow. In the history of sculpture there is no more direct or poetic expression of nature's rhythm.

7. Technical Developments After World War II.—"The modern artist is the counterpart in our time of the alchemist-philosopher who once toiled over furnaces, alembics and crucibles, ostensibly to make gold, but who consciously entered the most profound levels of being, philosophizing over the melting and mixing of various ingredients" (Ibram Lassaw, quoted by Lawrence Campbell in *Art News*, p. 66, The Art Foundation Press, New York, March 1954). While work in the older media persisted, it was the welding, soldering and cutting of metal that emerged after 1945 as an increasingly popular medium for sculpture. The technical and expressive potential of uncast metal sculpture was carried far beyond the earlier work of González and Picasso.

The appeal of metal is manifold. It is plentifully available from commercial supply houses; it is flexible and permanent; it allows the artist to work quickly and it is relatively cheap compared to casting. Modern metals also link sculpture to the stuffs of modern civilization and are emotionally related to that civilization. As the American sculptor David Smith has commented, "Possibly steel is so beautiful because of all the movement associated with it, its strength and functions. Yet it is also brutal, the rapist, the murderer and death-dealing giants are also its offspring" (quoted in Carola Giedion-Welcker, *Contemporary Sculpture*, Documents of Modern Art, vol. 12, p. 123, George Wittenborn, Inc., New York, 1955).

The basic tool of the metal sculptor is the oxyacetylene torch that achieves a maximum temperature of 6,500° F. (the melting point of bronze is 2,000° F.). The intensity and size of the flame can be varied by alternating torch tips. In the hands of a skilled artist the torch can cut or weld, harden and soften, colour and lighten or darken metal. Files, hammers, chisels and jigs are also used in shaping the metal, worked either hot or cold. The sculptor may first construct a metal armature which he then proceeds to conceal or expose. He builds up his form with various metals and alloys, fusing or brazing them, and may expose parts or the whole to the chemical action of acids. This type of work requires constant control and many sculptors work out and guard their own recipes.

Other sculptors such as Peter Agostini, George Spaventa, Peter Grippe, David Slivka and Jacques Lipchitz, who were interested in bringing into sculpture spontaneity, use of accident and automatism, returned to the more labile media of wax and clay, with occasional cire-perdue casting, which permit a very direct projection of the artist's feelings. The end result is often the creation of an informal image, bordering on the shapeless, in contrast to the often clean-cut shapes of metal sculpture. By the nature of the process the work is on a small scale.

Another modern phenomenon, seen particularly in Italy, France and the United States, is the revival of relief sculpture and its execution on a large scale to produce what might be called "environmental sculpture," intended to stand alone rather than in conjunction with a building. Louise Nevelson in her "Sky Cathedral" (1958), for example, employs boxes as container compartments in which she carefully disposes an assortment of forms and then paints them a uniform colour. In Europe the outstanding metal reliefs were those by Alberto Burri, Gio and Arnaldo Pomodoro, César Baldaccini, Zoltán Kemény and Manuel Rivera.

8. New Views of Nature.—Development of metal sculpture particularly in the United States led to fresh interpretations of the natural world. In the art of Richard Lippold and Ibram Lassaw, the search for essential structures took the form of qualitative analogies. Lippold's "Full Moon" (1949–50) and "Sun" (1953–56), the latter commissioned by the Metropolitan Museum of Art, New York, to hang in its room of Persian carpets, show an intuition of a basic regularity, precise order and completeness that underlies the universe. Lassaw's comparable interest in a galactocentric universe inspired his "Planets" (1952) and "The Clouds of Magellan" (1953).

In contrast to the macrocosmic concern of these two artists were the interests of sculptors such as Raymond Jacobson, whose "Structure" (1955) derived from his study of a honeycomb. Using three basic sizes, Jacobson constructed his sculpture of hollowed cubes emulating the elementariness, the general regularity but slight unpredictability and the surprising variety of the honeycomb.

Isamu Noguchi's "Night Land" is one of the first landscapes in sculpture. David Smith's "Hudson River Landscape" (1951), Theodore J. Roszak's "Recollections of the Southwest" (1948), Louise Bourgeois' "Night Garden" (1953) and Leo Amino's "Jungle" (1950) are later examples.

9. The Human Figure.—The variety of human forms in mod-

ern sculpture results in part from the intimate, personal nature of the sculptor's art and from the example of preceding artists in moving away from the imitation of the body. The thin, vertical, Etruscan idol-like figures developed by Giacometti after World War II showed his repugnance toward rounded and smooth body surfaces or strong references to the flesh. His men and women do not exist in felicitous concert with others; each form is a secret sanctum, a maximum of being wrested from a minimum of material. Reg Butler's work (such as "Woman Resting," 1951) and that of David Hare ("Figure in a Window," 1955) treat the body in terms of skeletal outlines. Butler's figures partake of nonhuman qualities and are fantasies of an unsentimental and aggressive character; the difficulties and tensions of existence are measured out in taut wire armatures and constricting malleable bronze surfaces. Kenneth Armitage and Lynn Chadwick, two other British sculptors, make the clothing a direct extension of the figure, part of a total gesture. In his "Family Going for a Walk" (1953), for example, Armitage creates a fanciful screenlike figure recalling wind-whipped clothing on a wash line. He is intrigued by flatness and takes pleasure in inducing wonder as to what is on the other side. Both Chadwick and Armitage transfer the burden of expression from human limbs and faces to the broad planes of the bulk of the sculpture. Chadwick's sculptures are often illusive hybrids suggesting alternately impotent De Chirico-like figures or animated geological forms.

Marino Marini and Luciano Minguzzi admire the amply proportioned feminine form. Minguzzi's women (*e.g.*, "Woman Jumping Rope," 1954) may exert themselves with a kind of playful abandon. Marini's (*e.g.*, "Dancer," 1949) enjoy a stately passivity, their quiescent postures permitting a contrapuntal focus on the graceful transition from the slender extremities to the large, compact, voluminous torso, with small rich surface textures.

The segmented torso, popular with Arp, Laurens and Picasso earlier, continued to be reinterpreted by Alberto Viani, Bernard Heiliger, Karl Hartung and Raoul Hague. The emphasis of these sculptors was upon more subtle sensuous joinings that created self-enclosing surfaces. Viani's work, for example, does not glorify body culture nor suggest macrocosmic affinities as does an ideally proportioned Phidian figure; his torsos are seen in a private way, as in his "Nude" (1951), with its large body and golf-ball breasts.

Perhaps the most impressive figure sculptures made in the U.S. between 1955 and 1960 were those by Seymour Lipton. Their large-scale, taut design and provocative interweaving of closed and open form restore qualities of mystery and the heroic to the human in a language and conception that seems right for an era of metals and a complex society.

10. Archaizing, Idol Making and Religious Sculpture.—After World War II several sculptors became interested in the art of early Mediterranean civilizations. The result was a conscious archaizing of the human form with the intent of recapturing qualities of Cycladic idols, early Greek and Egyptian statuary and some aspects of late Roman art.

Moore's admiration for archaic Greek sculpture produced "Draped Reclining Figure" (1952), which shows his return to the solid form and the suggestion of power and force by using drapery as a tense foil for the volumes that press against it. His "King and Queen" (1952–53) resulted from further excursions into the archaic Greek myth world.

The interest in recreating idols or totems was continued by Arp in his "Idol" (1950) and by Noguchi in his Stone Age-type sculptures for the Connecticut General Life Insurance company (Hartford, Conn.). By creating presences that elude rational definition, these artists restore to art its ancient and medieval aura of myth, mystery and magic in an age that consistently disclaims their existence.

The argument that modern sculpture is inappropriate for religious requirements is disproved by works of Lipchitz, Lassaw and Herbert Ferber. In keeping with the Jewish preference for nonfigural art, Ferber's ". . . and the bush was not consumed" (1951), commissioned by a synagogue in Millburn, N.J., comprises clusters of branches and boldly shaped weaving flames, invisibly suspended in a powerful and intimate vision that absorbs its viewers with its hypnotic rhythm. Lassaw's "Pillar of Fire," for the exterior of a synagogue in Springfield, Mass., also has a mesmerizing pattern recalling the induced images seen when gazing into fire. Lipchitz' sculpture of the "Virgin of Assy" (1948–54) was commissioned for the Catholic church at Assy, France.

Moreover, an increasing number of gifted sculptors are providing handsome liturgical objects and decorations, such as Harry Bertoia's shimmering reredos, Lipton's work for a synagogue in Tulsa, Okla., and Roszak's sculptured spire for Kresge chapel on the campus of the Massachusetts Institute of Technology, Cambridge.

11. Public and Private Memorials.—After World War II there was a flood of public memorial sculpture, and in Europe especially many of the commissions were carried out by modern sculptors. A striking war memorial in Italy is Mirko Basaldella's gate for the monument to the Roman hostages killed in the Ardeatine caves (1951). For its full effect the gate must be seen in connection with the rugged masonry wall to which it is attached. The gate is cast in metal and fashioned in a tangled, thicketlike pattern which suggests the painfully difficult passage from life to death for those who died in the caves.

Another imposing memorial is Ossip Zadkine's monument to the bombing of Rotterdam, a figure recoiling from the violence that descended from the sky. Moore's "Warrior With a Shield" defiantly raises his shield and mutilated body toward the ill-starred heavens during the battle of Britain. Epstein's public monument to "Social Consciousness" (1952–53), in Fairmount park, Philadelphia, treats the helplessness of those confronted with pressures over which they have no control. In contrast to the invulnerable champions of academic art, these sculptures image the hero in distress.

12. Other Developments.—Despite the rapid and exciting developments in both architecture and sculpture the two have seldom been meaningfully and integrally united. The architecture of Le Corbusier, Frank Lloyd Wright, Pier Luigi Nervi, Ludwig Mies van der Rohe and others occasionally shows strong sculptural qualities, but relatively rarely were their surfaces planned to receive sculpture. Free standing sculptures such as those created by Gabo, Pevsner, De Rivera, Calder and Noguchi have been used to provide intimacy and visual relief from the severity of the "cult of the cube" in architecture. The architectural firm of Skidmore, Owings and Merrill successfully used Bertoia's brilliant screens and Noguchi's sculptures and garden ideas; Roszak's "Eagle" for the American embassy in London and Moore's changeable reliefs on the London Time and Life building held out hope for further thoughtful integration of the arts.

Also of great moment is the phenomenon of the sculptor-designer who has produced important changes in furniture and industrial design. Max Bill's school in Ulm, Ger., showed great promise. Playground facilities have been revolutionized by such designs as those made by Noguchi for Creative Playthings Inc. in the U.S. and the slides, hollowed forms and climb apparatus of Egon Moeller-Nielson for parks in Stockholm, Swed. Noguchi, Moholy-Nagy, Bill, Bertoia and many other modern artists contributed to the breakdown of the distinction between the object of utility and the work of art. Not since Gothic times has sculpture shown such promise of becoming an extensive and important part of human existence.

SCULPTURE, SEPULCHRAL, a term descriptive of the figures of persons commemorated by sculpture or by linear cutting or by engraving on stone or metal slabs, either at floor level or on raised structures. The whole commemorative work may be a cenotaph or may contain or cover an interment. Among the

many ancient types of sepulchral monument the Etruscan form of the 6th and 5th centuries B.C., represented in the Flavian period by the Ulpia Epigone, is the nearest forerunner of the later Christian type in 15th-century Italy. There are good examples of Etruscan tomb monuments in the British museum but full-scale recumbent effigies of the dead were not a feature of Greek and Roman commemoration.

Medieval Effigies.—Full-scale recumbent effigies did not reappear in Europe until toward the end of the 11th century, when very interesting examples were found in Germany. There is a fine bronze grave slab of 1080 at Merseburg cathedral, and the dignified effigy of Wittekind, duke of Saxony, at Bielefeld, is late 11th century. Other interesting early examples of this period are at Quedlinburg and Magdeburg (1100–1300). There are three fine grave slabs of abbesses showing stiff and highly stylized drapery with long, hanging sleeves, at Quedlinburg. These slabs have delicate and well-carved conventional borders and their dates are between 1130 and 1150.

Among the very early ecclesiastical effigies in the cloisters at Westminster abbey is that of Abbot Crispin who died in 1117. It is of black Tournai marble and is believed to be the oldest recumbent effigy in England. Westminster abbey is extremely rich in the finest examples of most styles and periods, and the range of monumental art in and after the middle ages makes it the best single church in the world for the study of the subject.

In all countries and periods the figures representing kings, nobles, ladies, ecclesiastics, warriors, children, merchants, etc., are of the utmost value in the study of contemporary costume and armour and are only rarely archaic presentations of earlier styles; enthusiasm for antiquity revived Roman armour, togas, etc., in

the 17th and 18th centuries. Early history is that of the gradual emancipation from the flat slab shape which gave way to progressively higher relief toward the later 12th and mid-13th centuries; there are many examples in Germany and fewer surviving in Italy and France, but the much restored although still important series of royal tombs in the abbey of St. Denis, north of Paris, shows a further advance toward natural attitudes and finer treatment of drapery.

Germany was more conservative in adherence to the slab type but the English evolved splendid and vigorous figures of ecclesiastics, worked often in Purbeck marble, and also the famous mail-clad warriors sometimes in attitudes of partial activity or even of spirited action. The crossing of the legs has been wrongly supposed to be connected with the crusaders. There are fine examples of 12th- and 13th-century effigies at Ely, Salisbury, Wells and at other cathedrals, abbeys and parish churches.

In Italy, the Cosmati family made elaborate tombs with architectural canopies inlaid with mosaic and marble; beneath these, on a tomb-chest or a structure formed like a sarcophagus, there was often a recumbent presentation of the dead person coloured to show rich vestments. In 13th-century England the decoration was not achieved by mosaic but by painting and this became general by about 1300.

In France, apart from St. Denis, the medieval tomb-effigies are considerably rarer than in England. English canopied tombs, with the effigies raised on a tomb chest or rectangular structure for adding dignity to the design, are sometimes of quite elaborate architectural form; good examples are Archbishop de Gray at York and Bishop Giles of Bridport at Salisbury.

The 14th century was a period of great charm in sculptural developments and the richer tombs became soaring, pinnacled structures forming canopies over finely worked effigies in stone, wood or fine alabaster; magnificent examples are at Canterbury, York, Gloucester and, above all, at Westminster. Most medieval effigies have appropriate animals at their feet.

The opening of the century gave the superb royal effigies in gilt bronze in the Saints' chapel at Westminster; their contrasts with the Italian Renaissance figures of Henry VII and his queen in the same church and in the same material are important in the study of the different art forms. Another magnificent later example in bronze is Richard Beauchamp, 1454, at Warwick dated between the early Westminster bronzes and the Henry VII tomb by Torrigiano.

There are good examples of warriors in Exeter (1320) and Bristol (1300) and of ladies at Alnwick (1330) and at Westminster. Brasses abound and there is an especially fine group at Cobham, Kent. An English sculptor was employed for a papal tomb at Avignon. Very beautiful examples in stone are at Ewelme and in the Holland monument which was moved after World War II to St. Peter ad Vincula in the Tower of London.

The later effigies in the period are recumbent with the hands together in prayer, but there are a few interesting exceptions as at Tewkesbury where the effigy of Lord Edward le Despenser (1375) kneels with the hands in prayer under a high canopy on the roof of a chantry chapel. The removal of late coats of paint and varnish by R. P. Howgrave-Graham shortly before and after 1940 revealed a completely natural figure with fine lifelike face colouring and the eyes directed toward the altar. The attitude is unique at such an early date in England. In Bakewell, there is a very unusual wall monument showing only the upright busts of a knight and his lady in a canopied niche.

Weepers, sometimes representing relatives, must be included as effigies and were in some cases portraits, as seems probable in the gilt bronze statuettes on the tomb of Edward III at Westminster. These weepers surround monuments in standing attitude but are not necessarily shown mourning. About 1400 was produced the highly ornate tomb of Philip the Bold, duke of Burgundy, now in the Dijon museum, where intensely dramatic professional weepers were introduced for the first time by Claus Sluter.

The tomb of Philippe Pot, seneschal of Burgundy, in the Louvre, is in painted stone and brings into monumental sculpture the element of motion; the armoured effigy lies in the quiescent atti-

tude of prayer on a slab which is supported on the shoulders of bearers hooded and gowned as mourners and seeming to march in a funeral procession. They carry shields of arms. The date of this is about 1480.

The Renaissance.—In 15th-century Italy the architectural format of the Cosmati was transformed into a vehicle for relief sculpture of subtle and gentle beauty by such men as Agostino di Duccio; yet the same century, so curiously marked in much of its art by morbid insistence on death and bodily decay, emphasizes this with dramatic grimness, especially in northern Europe. The dead person appears in the full pomp of active life on a hollow architectural structure with openings making visible inside a cadaver, that is, a lean and emaciated figure or skeleton with decayed and shrunken flesh attached and with reptiles and worms infesting it. The contrast is enhanced by the dimness of light and the placing of the cadaver almost at floor level. The cadaver monuments are almost wholly confined to ecclesiastical dignitaries.

Classical grandeur and elaboration in monuments was developed fully in Italy long before anything comparable to it appeared elsewhere. Rich and costly marble was easily available and was of the utmost value in Renaissance exuberance. Symbolism and allegory appeared early in Italy in the Renaissance period, and the monument of Francis II, duke of Brittany, and his duchess (1502–07) in Nantes cathedral is a fine French example. The effigies on it are delicate in treatment and appear to be portraits. Very fine statues at the four corners symbolize Justice, Force, Prudence and Temperance. In Italy, the monuments of the great attain to extraordinary magnificence and the effigy tends to be a glorification of the man, sometimes without much of the earlier religious solemnity and devotion. He may even be seated on a life-sized horse raised high on, and within, elaborate erections of marble.

At the end of the 16th century and early in the 17th century, the fantastic and opulent splendour of Elizabethan and Jacobean monumental art was based on classical motives and the effigies were brightly painted as to faces and hands, armour and costumes being also highly coloured. The great and wealthy as well as ordinary merchants and citizens in England and France may kneel on their tombs: man and wife on opposite sides of a lectern below which the family of boys and girls pray, ranged in two rows of graduated size according to age, the boys on one side and the girls on the other. Each of these figures is a true monumental effigy and in some cases may be a portrait. Some of the grandest examples are in Westminster abbey where the tombs in the aisles of Henry VII have been brought back to their original almost gaudy splendour.

The whole concept of the treatment of monumental sculpture was changed by the powerful incidence of Michelangelo in the Medici chapel in Florence where the two figures sit in niches above and symbolic figures recline on broken pediments. While old forms continued, the new concepts gained ground in northern Europe. A bust of the deceased in a niche was common and as time went on the figures would sit, like Bernini's popes, recline on one elbow, swoon, stand or float heavenward encouraged and supported by lachrymose female figures or mourned by "well-to-do cherubs" weeping small bunches of marble tears.

A new symbolism surrounds the effigy which is often a finely sculptured and realistic portrait but may be reduced to a mere low-relief medallion cherished by a tearful female figure. Sculptural symbolism emphasizes death, loss and grief and is seldom religious in feeling, though epitaphs may be full of genuine piety.

The Neoclassical Revival.—In the neoclassical revival, represented in Italy by Antonio Canova (1757–1822), in England by John Flaxman (1755–1826) and in Denmark by Bertel Thorwaldsen (1770–1844), there was a chastened sobriety and increased reserve. (The 19th century, however, while giving examples of dignified and reverential treatment with careful portraiture, was often distinguished by vapidity and poor sentiment.) The depth to which the sculptured effigy could sink in the 18th century is seen in the Westminster monument of Sir Cloudesley Shovel; but Westminster contains a wealth of fine sculpture by famous 17th- and 18th-century artists who are fully dealt with by K. A. Esdaile (see *Bibliography*).

Portraiture in Monumental Effigies.—The earliest occurrence of portraiture in monumental effigies has been a controversial subject, and opinion has tended toward the belief that all tomb effigies were merely conventional until the 14th century was well advanced. It may be assumed that early portraiture was confined to the great and wealthy and that the numerous effigies turned out commercially from sculptural workshops were made to pattern, with minor variations as in the monuments on which they were placed. Notable disputed instances of early date are the superbly designed English effigies in cast bronze of Henry III who died in 1272 and of Eleanor of Castile (1291), both made by William Torel, a London goldsmith. The king's face is full of characterization which harmonizes with his known personality and, allowing for some stylization, it seems to show very clear elements of portraiture. Against this is the argument that it was made long after his death, but this is invalidated by the discoveries made about 1950. These discoveries were made during the restoration by Howgrave-Graham of the earlier funeral effigies that lay in state for royal obsequies in England and France and had always been accepted as the unimportant conventional handwork of craftsmen.

It was found that the faces of these effigies were of two kinds, two being cast from molds taken from the actual face very soon after death. The others were carved in wood from such death masks and all were finished and painted to simulate full life. At Westminster, these effigies were kept by the monks and so were available to the makers of the monuments and would naturally be used as models. The French effigies were preserved in a similar way by the monks at St. Denis, where the monarchs were buried. The view of Sir W. St. John Hope that a funeral effigy of Henry III was made would seem to suggest that it was the basis for Torel's bronze and that the tomb effigy is a somewhat stylized portrait in which his drooping eyelid was naturally ignored.

Portraiture seems likely in the effigy of Edward II in Gloucester cathedral, and the probability of portraiture as a frequent aim, at least of the great and the wealthy, is enforced by the skill and the interest in physiognomy found in portrait-corbels of 15th-century craftsmen in Lincoln and Durham cathedrals, in Westminster abbey and elsewhere.

In early monumental brasses, where the effigy is purely linear, portraiture is rare but it seems more usual in the incised stone and marble slabs that were made in northern France and are remarkably plentiful in the cathedral at Châlons-sur-Marne. (*See* SARCOPHAGUS; TOMB; SCULPTURE.)

Death Masks.—A death mask is a wax or plaster cast of a mold taken from a dead face. Death masks are true portraits, only requiring the correction of postmortem changes in the eyeballs. From ancient Egyptian times they have been made as aids to portrait-sculptors, and latterly as mementos of the beloved dead.

In medieval France and England actual death masks were used for the royal funeral effigies that lay in state, but the Westminster abbey series is unique, as the revolutionaries destroyed those in France. Some at Westminster served as models for wood carvers, but R. P. Howgrave-Graham's discoveries show that two are actual masks applied to the effigies.

The mask of Henry VII is probably the finest in existence, while that of Edward III is the earliest European example; it records the facial distortion due to his fatal stroke. From the 13th century, death masks provided models for the sculptors of tomb effigies.

SCULPTURE TECHNIQUES. The two basic methods of creating sculpture are the direct method—that is, by direct carving—and modeling, in which the piece is modeled in clay, or similar material, and is then reproduced in plaster, bronze or some other material.

This article briefly describes modeling, casting in plaster and bronze, stone carving, wood carving and certain modern techniques. These are the techniques used with the more common materials of sculpture. Clay modeling as described here is that done preliminary to casting; for sculpture in clay itself *see* TERRA COTTA. *See* also METALWORK, DECORATIVE: *Techniques of Metalworking.*

MODELING AND CASTING

Modeled Sculpture.—Generally, all sculpture that is to be cast in bronze or other metals or materials is first modeled in moist clay, plasteline or wax. Clean moist clay is preferred by the majority of sculptors.

In the time-honoured technique for modeling a small massive unit of sculpture, the sculptor kneads his moist clay until it has a smooth, consistent texture. He rolls chunks of clay into a number of loaf shapes and piles them up near his modeling stand, which is equipped with a turntable. He begins by bending and squeezing a few pieces of clay to form the main geometric shapes of his planned sculpture. He then breaks off smaller pieces of clay from his remaining clay pieces and builds up his sculpture shape, turning his clay model as he works and studying it from all angles so that the whole unit develops consistently. Detailed surface shapes and textures are developed until the clay model is finished.

FROM LOUIS SLOBODKIN, "SCULPTURE PRINCIPLES AND PRACTICE," © 1948, WORLD PUBLISHING CO.

ARMATURE FOR A STANDING MALE FIGURE WITH SOME CLAY ATTACHED

In larger sculpture an inner structure called an armature is built to support the clay, which otherwise would collapse from its own weight. A few blocks of wood nailed together, a heavy lead pipe or a galvanized iron pipe secured to a baseboard will serve as the armature for a life-sized head or similar sculpture unit. Larger pieces of sculpture are supported by more complicated armatures constructed of lead pipe, iron rods or pipes and wood. A combination of these materials is used in the huge armatures for monumental sculpture.

Clay models are sprinkled with water to keep the clay pliable while the models are being developed, and they are carefully wrapped in moist cloths between sessions of work. Plasteline and wax remain pliable without water and are the favoured materials for fragile, perforated sculpture units and for preparatory sketches for large sculpture. Plasteline

used for large sculpture does not need as much supporting armature as moist clay does.

The sculptor's most important modeling tool is his own thumb. Polished hardwood blades (carved from boxwood and similar fine-grained woods) are also used to apply clay. Bent wire tools doweled to wooden handles are used to help pull the surface of the clay together and for cutting away excess clay or gouging into the surfaces. While the main mass of clay shape is being organized the sculptor may use a crude block of wood or a paddle to pat and block his clay into shape.

When the model is completed it is cast in plaster, either by a professional plasterer or by the sculptor himself. (Ls. S.)

Plaster Casting.—The three methods of plaster casting are the waste mold, the gelatin mold and the piece mold. The waste mold is the simplest and is used where only one cast of the model is desired. (In the process the mold is destroyed.) Both the gelatin mold and the piece mold can be reused; the piece mold is the most complicated to make but gives an exceedingly accurate cast.

In all plaster casting the model is first covered with a coat of shellac, so that the mold does not stick to the clay.

FROM ARNOLD AUERBACH, "MODELLED SCULPTURE AND PLASTER CASTING"; ELEK BROOKS, LONDON

PLASTER CAST BY ARNOLD AUERBACH USING THE WASTE MOLD PROCESS: (TOP LEFT) CLAY MODEL WITH DIVISION LINE MARKED WITH METAL; (TOP CENTRE) COMPLETED MOLD; (TOP RIGHT) BACK HALF REMOVED; (BOTTOM LEFT) FRONT MOLD OPENED AND CLEANED; (BOTTOM, CENTRE AND RIGHT) PROGRESSIVE STAGES IN CHIPPING THE MOLD FROM THE CAST

Waste Mold.—Division lines are first made on the clay model with small pieces of brass, or a thin clay wall, so that the mold will be marked for cutting when it is finished. This line of division is across the top of the head and behind the ears. The model is then covered with a coating of coloured plaster, made by adding bluing or dry colour to the water with which the plaster is mixed. (Later, when the molder is chipping the plaster mold from the final cast, this coating warns him that he is near the cast and must chip carefully to prevent cutting into it.) Over the first coating of coloured plaster (about $\frac{1}{8}$ in. thick), a thicker coating of white plaster is applied. If the piece is large or has parts that would break easily, this coating is reinforced with other materials. When this coating has set, the mold is cut along the marked division line and is opened. The clay of the model is dug out carefully in order not to damage the mold. Then the mold is washed, soaped with green soap (melted in hot water) and allowed to cool. All the soap is carefully removed from the mold and a light coating of olive oil is applied to insure the proper separation of the mold from the final cast.

Various methods are used for the final casting. In one method used for a head, for example, the sections of the mold are put together and held in place by scrim dipped in plaster or tied with wire. The mold is then turned upside down and plaster of the proper consistency is poured in. If the model is small it may be entirely filled, thus forming a solid cast. Larger pieces may be cast hollow, the plaster being evenly distributed by continually turning the mold. A thickness of $\frac{3}{4}$ in. is sufficient to make a strong cast, especially if it is reinforced on the inside with burlap dipped in plaster or with iron pipes. When the plaster cast has set properly, the outer wrappings are removed and the plaster mold is chipped away with a mallet and chisel. The final cast may be retouched by wetting the cast and applying to it plaster of a thinner consistency than the casting plaster.

Gelatin Mold.—This procedure is much more complicated than waste molding: proper temperature of the gelatin and correct timing in opening the mold at every stage of the operation are essential. In addition, the sections of the cast must be keyed to each other with great precision.

A layer of clay filler, about $\frac{3}{4}$ in. thick, is first placed over the model, with a clay wall marking the line of division. This layer will subsequently be replaced by gelatin, so it must be even and without weak places.

Thereafter, the procedure, briefly described, is as follows. An outer shell of plaster is made over the filler, and when it has set the shell is opened and the clay filler removed. The sections of the outer shell are replaced in their original position around the model and are bound together. Casting gelatin is poured in through a hole in the top, filling the space between the model and the outer shell. When the gelatin has cooled, the shell is opened and the clay of the model is cleaned from the gelatin mold. The gelatin mold is then greased, and, with the shell to hold it, is put together again; then the plaster, mixed to the proper consistency, is poured into it. When the plaster has set, the mold is opened and lifted away from the cast. After the mold is cleaned and greased it can be reused for casting.

Piece Mold.—As the name implies, a piece mold is made in small pieces which are then reassembled for the final casting. The process is very complicated and can be done only by persons who are skilled in working with plaster. The caster begins by determining how many pieces are required for the model he is working on, and then he makes them, one at a time, using a wall of clay or plasteline to mark off the area of each piece. The pieces, which are made of plaster, are then reassembled and an outer shell is

made to hold them in place while the final plaster cast is being made. After each casting the pieces are cleaned and oiled in preparation for the next casting. Of the three methods of plaster casting, this is the most accurate. Its other advantages are that the mold may be reused and will last indefinitely, where gelatin molds deteriorate in a short time.

Finishing and Colouring.—The plaster cast may be either an intermediate stage or the final stage of the piece of sculpture. If the cast represents an intermediate stage, it is later cast in bronze, or some other material, or reproduced in stone, as described in following sections of this article. If the plaster cast is the final stage, it is finished to resemble bronze. Of the various methods of doing this, the most common is the oil-paint method. One coat of shellac is applied as a prime. After this has dried, a coat of brown oil paint is applied and allowed to dry. If a greenish blue tint is desired, a very thin mixture of light-green oil paint is applied to the brown coat. When this is almost dry it is wiped off lightly with a rag, allowing the green colour to remain in the deep parts. For a metallic effect, a little gold or bronze powder mixed with dryer may be applied to the high parts. When the piece is thoroughly dry it is rubbed with wax, which subdues any unpleasant shiny effect. Similar procedures may be used to apply any other desired colour.

Bronze Casting.—Next to stone, the most popular medium with sculptors throughout the ages has been bronze, an alloy made up principally of copper, with tin, zinc and lead in varying proportions. (The most common formula is 85% to 90% copper and from 10% to 15% tin, zinc and other nonferrous metals.) The popularity of bronze is due to its permanence and the freedom of expression it gives the artist. Its tensile strength is high, which makes possible a movement that would be impossible in stone; it is comparatively light and therefore adaptable to many uses; and it affords a wide variety of surface finishes.

Metal casting is a highly technical operation that requires much special equipment and is done in foundries by skilled craftsmen who usually each specialize in one phase of the operation. There are two methods, the *cire-perdue*, or lost-wax, method and the sand process. *Cire-perdue*, the older method, is considered especially good for reproducing faithfully delicate and intricate detail, but the results obtained from either method depend to a very large extent upon the skill of the craftsman.

"Cire-Perdue" Casting.—After the foundry receives the piece of sculpture (usually in the form of a plaster cast), the first step is the making of a gelatin mold. For smaller sculptures, this mold is made of the whole piece; for larger sculptures, the model is divided into sections and a mold is made of each section. The gelatin mold, which bears the details of the model in reverse, is then cleaned and made ready for the wax cast.

For the wax cast, the inside of the gelatin mold is painted with molten wax which is then reinforced with sheets of warm wax pressed against it. The thickness of the wax must be controlled so that it does not exceed the desired thickness of the final cast in bronze. (The bronze in a one-foot-high statuette, for example, is about ⅛ in. thick; for larger pieces the thickness increases but seldom exceeds ½ in.) The gelatin mold is then taken off, leaving a hollow wax replica of the sculpture, which the sculptor may retouch if he wishes. At this stage, gates and vents in the form of wax rods are attached to the figure in such a way as to carry off the melting wax during the baking of the final mold.

The final mold is made of a heat-resisting semiliquid silica compound poured into the wax mold to form the core and built up around the outside to form a jacket. This entire mass is put into a brick fire chamber and baked for two or three days until the wax has melted away. The mold is then removed from the oven and is packed in sand and earth in a floor pit. The molten bronze is poured from crucibles into a large opening in the mold and runs through the gates, filling the space left empty by the melting of the (lost) wax cast. When the bronze has cooled, the silica jacket is broken away, the core is tapped out and the bronze is dipped in acid for cleaning. The piece is then touched up with hand tools, by a craftsman or by the sculptor himself. At this stage the seams and rods of crude bronze formed by the gates and vents are removed and any defects in casting are dealt with. The piece is then ready to receive its patina, as described below.

Sand Process.—This is similar to the piece-mold process of plas-

ter casting. The mold is made by gently hammering against the sculptor's original model a very fine damp French sand, a composition of clay, silica and alumina, which when it dries becomes quite hard. The mold is made in two halves—usually the front and the back of the piece. For each half, the mold is divided into several pieces, the size and shape of which are governed by the shape of the model. These pieces, which are usually about two inches in thickness, are removed from around the plaster model and are reassembled in a containing iron frame called a flask. The flasks for each half of the sand mold will fit together exactly, and when assembled are held together tightly by clamps and bolts.

Inside each sand mold there is built up a core of sand, so shaped as to leave space for the bronze between the core and the mold (or the core may be made exactly the size of the mold and then shaved down). The core is suspended inside the mold with pins going through the core and the mold. Grooves are made for the bronze to enter, and gates and vents are added for escaping gases. All of this—mold and core—is baked for several hours until it is hard. Molten bronze is then poured in, filling the space between core and mold. When the bronze has cooled, the sand mold is removed and the finishing proceeds as in *cire-perdue* casting.

The sand process is frequently used for very large sculptures; these are cast in sections which are then welded together.

Patina.—Bronze will naturally become dark and beautiful, but because this requires a long period of time most sculptors colour their casts. The copper and copper compounds in the bronze make possible many variations of green, red, black, brown and blue. One method for producing a patina is to heat the bronze with a blow torch and while it is heated apply acids with a brush. The bronze is washed with water at intervals to keep the application of acids thin. For outdoor sculpture a method of applying the acids on a cold metal is preferable.

During the Renaissance and earlier, the gilding of bronze was popular, gold leaf being applied to the surface with an adhesive medium. The same method is used in silver gilding.

Another gilding process, which was used by Lorenzo Ghiberti, Benvenuto Cellini and others, is fire gilding: an amalgam of gold and mercury is applied to the surface of the bronze with a brush and the metal is then heated until the mercury evaporates, leaving the gold fused with the bronze surface. Paduan and Florentine bronzes of the Renaissance were sometimes painted with lacquer which gave a rich brown colour. Polychromatic effects may be achieved by the inlay of other metals and alloys, such as silver, copper, niello and electrum. (J. A. C.)

STONE CARVING

Direct Carving.—The sculptor begins by marking on all sides of his block of stone (with greaseless chalk or opaque water colour) a rough outline of his planned sculpture composition.

If he is working in marble, limestone, sandstone, alabaster or other soft stone, he then proceeds as follows. With a pointed chisel and his stone mallet he knocks off the big chunks of stone that are not included in his composition. Then with his pointed chisel held at an acute angle to the stone (almost parallel to the surface) he roughs out the approximate shape of his sculptural idea, with constant attention to the grain or stratification of the stone or marble. (A misdirected chisel may split a brittle marble or ruin a stone.) He carves always around the stone, crisscrossing the direction of his chisel point as he carves. When he has roughed the stone down to about an inch from the final surface, he carves with his tooth chisels. He perfects the shape as well as he can with his tooth-edged chisels and at last he carves with various-sized flat straight-edged chisels. All through his carving the sculptor keeps a sharp edge on his chisels. The stone is finished with straight-edged chisels, rasps, files and abrasives and is perhaps polished with pumice.

In working with granite, which is composed of hard crystals fused together by great heat and pressure, the sculptor cannot cut across the surface the way he carves the softer, stratified stones. The crystals must be broken by pounding directly into the block. A granite block is roughed out with a heavy pointed chisel (called a bull point); then the granite crystals are crushed further with a pick (a hand hammer with a pickax head) and then with a bush hammer (a heavy square-headed hammer with a waffled striking face). The granite sculpture is finished with chunky flat-tipped chisels and mallet. Finally, it may be polished with carborundum stones and other abrasives. (Ls. S.)

BY COURTESY OF MALVINA HOFFMAN

THE POINTING PROCESS FOR STONE CARVING: (TOP) POINTING MACHINE HUNG ON ORIGINAL MODEL; (CENTRE) POINTING MACHINE TRANSFERRED TO MARBLE; DRILLING IN PROGRESS; (BOTTOM) USING TOOTH CHISEL AND METAL HAMMER TO REMOVE SURFACE BETWEEN POINTS

Pointing.—In stone carving done by the pointing process, a model or plaster cast is made and is then reproduced in stone with the aid of a measuring device called a pointing machine. As a technique of creative sculpture it has limitations, but it has been much used, especially in the 19th century.

With the pointing machine, three fixed points are established on the model: one at the uppermost extremity (the top of the head for a bust or upright figure) and two on the base, at opposite horizontal extremities. Mounds of plaster protrude about one inch from the finished surface of the model at these points. Metal sockets are imbedded in the mounds to secure the three fixed pins of the pointing machine: the one on top to receive the downward pointing pin and the ones at the bottom to receive pins extending from the lower horizontal bar. Three similar sockets to coincide with those on the model are placed in the block of stone. The three sockets will hold the pointing machine fast, so that the movable pointer may be manipulated to locate a point anywhere on the model.

When a desired point is located on the model (the first points are usually those which protrude the farthest, such as the nose) the movable pointer is fixed securely with screws. The pointing machine is then attached to the block of stone and a hole is drilled into the stone deep enough to allow the end of the pointer to slide forward to the same position that it did on the model. Other points are established in the same way until the stone is drilled with many holes, the bottom of each corresponding to a point on the model. The block may then be cut away until the bottoms of the holes are reached and the statue is thereby roughed out. The first points are established some distance away from what is to be the final surface. As the carving progresses the points are increased in number until an accurate reproduction of the model is attained in stone. The final points on the stone are usually left about $\frac{1}{32}$ in. higher than those on the model in order to enable the sculptor to put the finishing touches on the stone himself. (J. A. C.)

WOOD CARVING

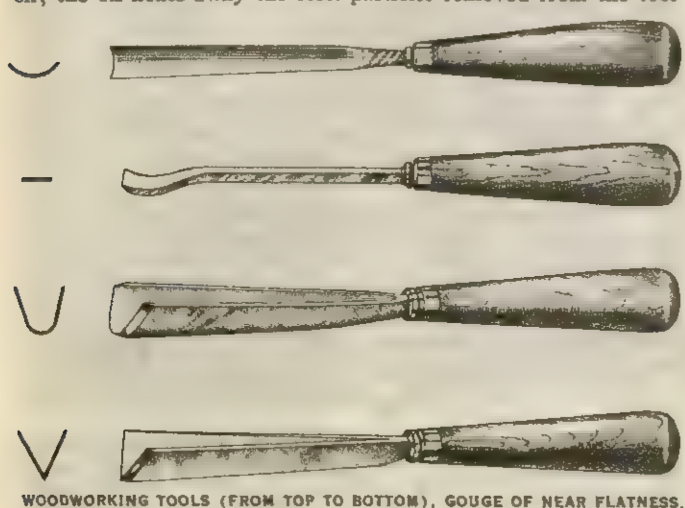
A suitable wood and several tools are needed for transforming the artist's conception into a wood carving. It is of the utmost importance that the idea or design selected be capable of execution in the block of wood chosen, for while it is possible to force an idea

upon a piece of wood, it is much better to use its natural beauty and structure as an aid in designing the carving. Thus, if a figure or animal is to be portrayed in wood, the design should be somewhat abstract; academic or realistic results are not easily attained except in relief carving because of the limitations of the material.

The problems that arise in carving are those of related forms and planes. An experienced artist may solve these as he works, letting the idea develop from the shape and grain of the material, but a less experienced sculptor will do better to first work out a full-size sketch in soap or plaster. After the elementary problems of placement have been solved, the carver proceeds to transfer the idea to the wood, and in so doing makes any changes that are needed to improve the idea. In most cases it is possible to eliminate details that do not contribute to the finished effect. The use of many details in carving proclaims either the amateur or the skilled carver with little imagination.

The wood itself should be of dense, even grain, such as mahogany or walnut, and must be seasoned; green or unseasoned wood will crack and split as the carving progresses, owing to evaporation of moisture. The moisture content varies with the wood and with the humidity. Wood will also absorb moisture and expand or swell, thus changing the contours of a piece of sculpture; for this reason air-dried wood, which absorbs less moisture, is preferred to kiln-dried wood. The colour and prominence of the grain is also to be considered. A wood with a distinct grain is sometimes more suitable for a carving with simple forms that utilize the markings as part of the design; in a more intricate carving the design would be lost in the confusion of grain and detail. Burls, roots and crotches are utilized for their unusual markings and necessitate a very carefully conceived design to produce a fine work. Knots and checks (cracks caused by shrinkage) can be used or ignored, unless they interfere with the design. Cracks can be filled with wood putty or stick shellac which comes in colors to match the wood. Wood with an alternate hard and soft grain is to be avoided; the chisel will cut the hard grain and compress the soft, causing small holes that are very hard to remove or conceal. Contrary to what might be thought, a soft wood is not easier to carve; razor-sharp tools are required to cut it, whereas a hard wood will cut easily. In carving, the best procedure is to cut across the grain rather than with it; this method makes for a consistent control over the cutting action of the chisel or gouge and will enable the carver to achieve a better and more even texture on the finished wood.

As for tools, a great number are manufactured, but the beginner needs a minimum of three—a gouge of near flatness, a deep gouge or fluter and a flat chisel, preferably a skew chisel. A sharpening stone will also be required to keep the tool edges in condition. Tools are usually supplied ground sharp but not honed—which means that the final cutting edge must be put on the tools by the carver. This is done by moving the tool back and forth over a fine stone called a hone, which is kept well oiled with a light machine oil; the oil floats away the steel particles removed from the tool



WOODWORKING TOOLS (FROM TOP TO BOTTOM). GOUGE OF NEAR FLATNESS, FRONT BENT CHISEL, TWO DEEP GOUGES

edge and thus preserves the cutting action of the stone. The dirty oil must be removed with a cloth, and new oil added. The tool should be held at the angle to which it has been ground on the bevel side and rubbed along the length of the stone (with a slightly rotary motion in the case of the gouges). The rough edge on the inside of the tool may be removed by the use of a slip stone, which comes in various shapes to fit the different tools. Tools should be of the best quality, and once sharpened will not need more than a few minutes care for each carving. Also needed is a mallet, which should be made of wood, plastic or rawhide to prevent damage to the ends of the tools when they are struck.

After the wood has been selected, a study of the grain will be helpful in placing the design. By looking at the end of the block one can see the circular ends of the grain, and by visualizing the effect of cutting into a series of cylindrical planes one can determine the result of the markings. This may seem complicated, but by continued observation the carver can learn to predict the finished result with great accuracy. The next step is to outline the design on the block with chalk, making allowance for the roundness. If a band saw is used to cut along the lines, the result will be a flat surface where it should be round. To prevent this, the carver should use a deep gouge to cut into the block along the lines of the design, never in a perpendicular to the surface but always at an angle. This will allow the forms to grow and often appear larger than the original flat surfaces. Tearing or splitting of the wood is an indication of dull tools. In case of a knot, the carver should work around it from all directions to prevent pieces from loosening or coming out. After the forms have been roughed out with the deep gouge, the shallow gouge is used to finish the carving. The skew chisel is used to get into corners where two or three planes meet.

If the carver prefers to leave the tool marks, they should be cut of even width and should present an over-all pattern that does not detract from the forms of the carving. If a smooth finish is desired, a shoemaker's rasp and riffler rasps are necessary to obtain a fine even surface. Rifflers come in various shapes to enable the carver to reach into small crevices, but a coarse garnet paper can be folded and used as well. After the rasping and filing, the carving is sanded with various grades (textures) of garnet paper. The last paper used should be a very fine one which will impart a glasslike finish to the carving. Sanding is always done with the grain to avoid scratch marks. The final step is to fill the cracks with stick shellac of matching colour and then give the entire carving a coat of clear or coloured wax. The wax should be allowed to dry in for ten days and then should be polished with a soft cloth. Many coats of wax can be added; in case of water spotting, the wax can be removed with solvent and the carving rewaxed. (J. A. Go.)

MODERN TECHNIQUES

In the 20th century, experimentation with materials—for special artistic effects and also in search of materials less expensive than the traditional ones—occasioned experimentation with techniques as well. Wrought iron has been used by Julio González, among others, using traditional ironworking techniques to produce sculpture. "Cast stone," used by Wilhelm Lehmbruck and others, is made of ground stone, sand and portland cement, in varying proportions, and is cast solid in a piece mold.

Many modern pieces are made of several materials. Alberto Giacometti's "The Palace at 4 A.M.," for example, is constructed in wood, glass, wire and string. Mobiles are constructed of various materials, such as wire, iron, sheet steel, steel rods, sheet aluminum and the like, which are so balanced as to move gently in space; the form is said to have been originated by Alexander Calder. Another modern technique is welding. (*See* SCULPTURE: *Technical Developments After World War II.*) (X.)

Sculpting in Plaster.—Working directly in plaster of Paris is another method used by some modern sculptors. The technique has a great deal to recommend it. The speed at which the plaster sets gives the work a great sense of immediacy and enables the sculptor to translate and achieve his original idea quickly; the material can be carved as well as modeled in the final stages; and,

finally, if the piece is to be cast in bronze, the process of plaster casting is eliminated.

In this method, a strong armature of iron must be constructed, preferably by welding, and should be painted with Brunswick black or an equivalent as a protection against rust, which would eventually rot and discolour the plaster. In roughing out the general bulk of the figure, wood-wool soaked in plaster may be used; this gets the sculpture up to size very quickly and, as the wood-wool is porous, makes the final result much lighter. At this stage any available padding, such as odd scraps of wood, can be used. In the beginning small quantities of plaster should be mixed because it sets quickly (in about five minutes unless size has been added). When the freshly mixed plaster begins to thicken it can be applied to the armature with large metal spatulas or builders' plastering tools. (Wooden tools are not suitable.) After a thickness of plaster has been built up over the armature, larger quantities may be mixed, as the new plaster adheres more readily to the plaster already there.

Before work is resumed on a plaster figure that has dried, it must be soaked very thoroughly with water; otherwise the old plaster will draw the moisture out of the new and cause it to crumble. (El. F.)

SCUNTHORPE, a market town and municipal borough (1936) in the Brigg parliamentary division of the Parts of Lindsey, Lincolnshire, Eng., 28 mi. N.W. of Lincoln by road. Pop. (1961) 67,324. Area 12.3 sq.mi. Parts of the parish church date back to the Middle Ages, notably the 12th-century pillars and the 13th-century porch. In 1871 the population was only 616, but with the discovery of ironstone in the area toward the end of the 19th century, the foundations of the iron and steel industry were laid. Subsidiary industries are the road-making and building materials industry, tar and benzole distillation, light engineering, and the manufacture of clothing and footwear.

SCURVY (Scorbutus) is a vitamin-deficiency disease characterized by debility, blood changes, spongy gums, and hemorrhages in the tissues of the body. In former times scurvy was common and often fatal among sailors. It has also occurred among soldiers on campaign, in beleaguered cities, among communities in times of scarcity, and in prisons and other public institutions. It was early recognized that scurvy and diet were connected, but it was not known until 1932 that the cause is deficiency of vitamin C (ascorbic acid; *see* Vitamins). This explains the occurrence of scurvy when fresh vegetables or fruit—rich in vitamin C—are unobtainable and its disappearance when they are administered.

The symptoms come on gradually with failure of strength, and mental depression. Then follow sallow complexion, sunken eyes, tender gums, and muscular pains. These symptoms may continue for weeks, gradually worsening. Teeth fall out and hemorrhages, often massive, penetrate muscles and other tissues. Disorders of vision, particularly night-blindness, may occur. The last stages of scurvy are marked by profound exhaustion, fainting, and complications such as diarrhea and pulmonary or kidney troubles, any of which may bring about death. Even in desperate cases, however, recovery may be anticipated when the deficient vitamin is supplied, by injection or orally (vitamin pills or amended diet).

The regulated administration of lemon juice in the British Navy, begun in 1795, had the effect of virtually extinguishing scurvy in the service. Lime juice—lower in ascorbic acid—was substituted in 1865, perhaps for reasons of economy, and British sailors were widely nicknamed "Limeys." Similar regulations introduced by the British Board of Trade in 1865 benefited the mercantile marine.

SCUTAGE (Escuage) (French: écuage, from Lat. *scutum*, a shield) means "shield money" and was in feudal law the pecuniary commutation of the military service due by the holder of a knight's fee (*see* Knight Service). A lord might accept from his vassal a sum of money (or something else of value, often a horse) in lieu of service on some expedition. The system was advantageous to both sides and grew rapidly with the expansion of money economy in Europe in the 12th and 13th centuries.

Scutage was taken in various countries, including France and Germany, but was most highly developed in England, where it is first mentioned in 1100. It seems to have been levied at first on ecclesiastical tenants in chief, who had difficulty in finding their full quota of knights for the king's army. It soon became a general tax on knight's fees and fractions thereof. The amount varied, but was usually one mark (13*s.* 4*d.*) or one pound silver on the knight's fee. Henry II (1154–89) once took two marks (1159) and King John (1199–1216) sometimes three. This latter rate became standard after 1246. Though the crown could demand scutage, tenants could not refuse to perform military service if it was required. But from the time of Richard I (1189–99) special "fines" (payments larger than the routine scutage) were accepted from tenants in chief in lieu of service on a particular campaign. As a result of the frequent and heavy scutages exacted by King John, clause 12 of Magna Carta (1215) forbade the levy of scutage without the consent of a great council. During the 13th century scutages and fines continued, the latter becoming more general. Scutage, collected from mesne tenants who had not attended a campaign, was divided between the king and those tenants in chief who had served in person. But by the 14th century scutage was becoming obsolete. It had also been of legal importance as the test (according to the lawyer Henry de Bracton) of tenure by military service. *See* also Feudalism.

SCUTARI: *see* Shkoder.

SCUTARI, the name formerly used for Uskudar (*q.v.*), a town of Turkey on the Asiatic shore of the Bosporus, opposite Istanbul. The name Scutari came into use toward the end of the Byzantine Empire. Scutari was the base (1854–56) of the British Army during the Crimean War and the site of the military hospital made famous by the work of Florence Nightingale (*q.v.*).

SCYLAX of Caryanda (in Caria) (6th century B.C.), ancient Greek explorer who was a pioneer in geography and the first Western observer to give an account of India. It is known from Herodotus that he was sent by Darius (*c.* 515 B.C.) to explore the course of the Indus and that he returned by sea after two and a half years to the Isthmus of Heroonpolis (Suez). References in ancient authorities seem to show that he left a record of his voyages, but none of the references is even nearly contemporary and it is difficult to say in what manner knowledge of Scylax was transmitted. The few fragments suggest a work in the form of a *Periplus* (mariner's coastal guide), with some geographical and ethnographical description and, in the account of India, some element of the fabulous. The extant *Periplus* which has come down under his name cannot, however, be the work of Scylax of Caryanda. It is a compilation of matter of various dates completed about 350 B.C. Though dry and practical, it is of considerable interest in form and language as the earliest surviving example of this branch of technical literature.

The Suda Lexicon attributes to Scylax a work on the Carian Heraclides of Mylasa, who distinguished himself in the revolt against the Persians (498 B.C.) and possibly in the second Persian War (480 B.C.). That the explorer and geographer was a pioneer also in historical-biographical literature is improbable.

Müller, *Geographi Graeci minores*, vol. i, pp. 15–96 (1885). *See* also F. Gisinger in Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft*, 2nd series, vol. 2, col. 619–646 (1927); J. Oliver Thomson, *History of Ancient Geography* (1948). (Ar. Ca.)

SCYLITZES, JOHN (fl. 2nd half of the 11th century), Byzantine historian, was the author of a *Synopsis historiarum* dealing with the years 811–1057. Known as the "Thracesion," *i.e.*, apparently originating from the Thracesion theme in Asia

Minor, he was a high officeholder at the Byzantine court, being described in manuscripts as *curopalates* and *drungarios tes vigles* ("commander of the imperial guard"). According to George Cedrinus (*q.v.*) he was also a *protobestiarios* ("grand chamberlain"). He was known as a contemporary of Michael Psellus (*q.v.*) and may have written a legal work for Alexius I in 1092.

In his history he drew on the work of Theophanes Continuatus for the early part, and then largely relied on sources no longer extant and on contemporary oral tradition. In some manuscripts the work is extended to cover the years 1057–79; this section is of little independent value and is known as *Scylitzes Continuatus*. There is no edition of the Greek text of this important historian, who is known through the almost literal reproduction of his work by George Cedrinus.

See bibliography and list of manuscripts in G. Moravcsik, *Byzantinoturcica*, 2nd ed., vol. i, pp. 335–340 (1958); G. Ostrogorsky, *History of the Byzantine State*, p. 188 (1956). (J. M. Hy.)

SCYLLA AND CHARYBDIS, in Greek mythology, the two immortal and irresistible monsters who beset the narrow waters traversed by Odysseus in his wanderings (later localized in the Strait of Messina, Scylla being on the Italian and Charybdis on the Sicilian shore).

Scylla, daughter of Phorcys and Cratais, is a supernatural creature, with 12 feet and 6 heads on long snaky necks, each head having a triple row of sharklike teeth, while her loins are girt with the heads of baying dogs. From her lair in a cave she devours whatever ventures within reach, and takes toll of six of Odysseus' companions. She is sometimes said to have been originally human in appearance, but transformed out of jealousy through the witchcraft of Circe or Amphitrite into her present shape. She is apt to be confused with the quite distinct Scylla who betrayed her father, King Nisus of Megara, out of love for Minos.

Charybdis, lurking under the fig tree a bowshot away on the opposite shore, drinks down and belches forth the waters thrice a day and is fatal to shipping. The shipwrecked Odysseus barely escapes her clutches by clinging to a tree until the improvised raft which she has swallowed floats to the surface again after many hours.

Charybdis is an imperfectly personified whirlpool. Scylla was often rationalized in antiquity as a rock or reef. Both give poetic expression to the dangers confronting Greek mariners when they first ventured into the perilous and uncharted waters of the western Mediterranean. The proverbial use of Scylla and Charybdis for the hazards attending any deviation from the true course is as old as St. Augustine. (D. E. W. W.)

SCYPHOZOA: *see* COELENTERATA; JELLYFISH.

SCYTHIANS, a people who during the 8th–7th centuries B.C. moved from central Asia to southern Russia, where they founded an empire that survived until they were gradually overcome and supplanted by the Sarmatians (*q.v.*) during the 4th century B.C.–2nd century A.D.

Until the 20th century most of the information concerning the Scythians, as the Greeks called them, or the Sakas as the Persians termed them, was based on the knowledge that Herodotus acquired when he visited Olbia, a Greek city founded *c.* 645 B.C. at the confluence of the Bug and Ingul rivers. He incorporated all that he had learned about them into the fourth book of his history. In modern times the work carried out in Siberia by Russian scholars and archaeologists produced so much new information that the word "Scythian" is often extended to include the nomadic kinsmen of the Scythians who remained in central Asia when the latter moved into Europe.

In its exact context the term "Scythian" should, however, be applied only to the tribes that settled in what is now southern Russia. The excavations begun in 1929 at Pazyryk in the Altai by M. P. Gryaznov and resumed in 1947 by S. I. Rudenko proved that the culture, art, and way of life of the tribesmen who continued to live in western Siberia and the Altai when the bulk of the Scythians marched into Iran and southern Russia remained closely akin to that of the migrants, the entire community being of Iranian origin and sharing a common language. Herodotus attempted to distinguish between the various tribes that settled in what later became Russia, and he was able to name among others the Callipidae, the Alazones, the Aroteres, the Neuri, the Androphagi, and the Melanchlaeni, defining the areas that each inhabited. These western Scythians carried on a lively trade with those who had remained in central Asia.

History.—In the 9th century B.C. the Scythian and kindred tribes were probably concentrated somewhat to the east of the Altai, but it was not until the Chinese emperor Hsüan Wang (827–781 B.C.) decided to send an armed force to curb the fierce Hsiung-nu, who had begun to make a practice of raiding China's western boundaries, that the Scythian nomads became restless. When the Hsiung-nu were forced back from the Chinese frontier and, in retreating, dislodged the Massagetae, who occupied the grazing grounds to the north of the Oxus (Amu-Darya) River, and when the latter in their turn assaulted their immediate neighbours, the Scythians, a wide-scale nomadic migration was set in motion. There is reason for thinking that the struggle for grazing land was rendered more acute by the beginning of a severe period of drought and that this factor may well have decided the Scythians to move westward in search of satisfactory pasture instead of remaining to fight for their traditional rights.

The Scythians were accomplished horsemen, having been among the earliest people to master the art of riding. Their mobility gave them a great advantage over their neighbours, so that when they eventually advanced westward across the Oxus they moved so fast that both Herodotus and contemporary Persian sources refer to the remarkable suddenness of their appearance on Iran's northeastern border. Their advance brought the Scythians into fierce conflict with the Cimmerians (*q.v.*), who had for centuries enjoyed possession of the Caucasus and the plain lying to the north of the Black Sea. But the Cimmerians still fought on foot and the Scythian cavalry quickly gained the upper hand. Some Cimmerians retreated through the Daryal (Dariel) Pass and were pursued across the Volga, where the Scythians were able to destroy and supplant them.

Meanwhile another Scythian force chased the rest of the Cimmerian Army across Urartu (Armenia), while a third entered the Derbent defile and reached Lake Urmia some time during the reign of King Sargon of Assyria (722–705 B.C.), linking up there with the second contingent to continue the fight against the Cimmerians. Thus strengthened, the Scythian troops were able to force the Cimmerians into a steady retreat which lasted for about 30 years, ending only when both combatants had reached the borders of Assyria. Then the Scythians formed an alliance with King Esarhaddon of Assyria (reigned 681–669 B.C.), but they soon abandoned this and concentrated on destroying the Cimmerians, giving the latter no respite till they had forced them back across Phrygia into Lydia, where they were finally wiped out.

This astonishing series of victories brought great fame to the Scythians. Their chieftain Partatua (Bartatua) and his son Madyes were quick to take advantage of it by setting themselves up as rulers of Urartu and all the lands stretching to the Halys (Kizil Irmak) River, establishing their capital at Saqqez. They invaded Syria and Judaea *c.* 625 B.C. Later they reached the borders of Egypt, but Psamtik I (663–610 B.C.) wisely decided to check any further advance by purchasing peace terms from them.

Meanwhile the Medes had become masters of Persia. They considered that the Scythians' increasing might presented a real threat to their own security, and they decided to concentrate their efforts in launching a decisive attack against the tribesmen. Their better-disciplined troops eventually contrived to push the Scythians northward back through Urartu, whence they had first appeared. Although the nomads thereby lost the control they had wielded during the previous 28 years over most of Asia Minor, their lands still stretched from the Persian border, through the Kuban into most of southern Russia. When forced by the Medes to retreat, some of them likewise settled between the Caspian and the Aral seas, where they intermingled with their Dahae kinsmen to produce the people who, some three centuries later, were to become known as the Parthians, while others penetrated into India and established kingdoms there (*see* SAKA).

The Scythians who settled in the Kuban and southern Russia quickly attained a position of importance. Many of them became extremely prosperous. Graves of the 7th–6th centuries B.C. situated in the Kuban abound in objects of gold and other precious materials, and although a form of patriarchal rule remained in force, it is clear that a class of wealthy chieftains or nobles was beginning to come into being there. In the 6th–5th century B.C. the richest burials were in southern Russia and the Crimea. These are associated with a relatively small number of Scythians who, as the Royal Scyths, established themselves as rulers of the area. Isolated groups of their tribesmen penetrated as far as what became Hungary and East Prussia. The kingdom of the Royal Scyths developed into a community which was to enjoy considerable economic power till the 1st century or so B.C. Its political importance was established when it was able to resist Darius on his invasion of Scythian territory about 513 B.C.; the Scythians resorted to a scorched-earth policy, which enabled them to withstand the Persian onslaught and obliged Darius to beat a hasty retreat in order to preserve his army. His consequent withdrawal from the plain lying to the northwest of the Black Sea left the Scythians in control of it; some of the Greek cities of the Pontus even had to pay the Scythians an annual tribute in order to preserve their independence. Scythian power remained paramount there till the 4th century B.C. when the Sarmatians appeared on the Don. Thenceforth the new invaders began steadily to increase their pressure on the Scythians till, in the 2nd century B.C., they managed to confine them within the Crimean area, gradually supplanting them as rulers of the plain until, in the 2nd century A.D., they finally succeeded in destroying the last remnants of this once powerful community.

The Royal Scyths.—Though the patriarchal order and the nomadic way of life remained general, the Royal Scyths were ruled by a sovereign whose powers were transmitted to his son. He was surrounded by a group of wealthy nobles who were virtually his courtiers. The dynasty claimed descent from Targitaus, the founder of the house of Phalatae; but Targitaus was probably a legendary figure, and it is more likely that Colaxis was the first of the royal line. He was succeeded by Spargapeithes, who handed the crown to his son Lycus, who in turn passed it to his son Gnurus at about the time when Partatua and his son Madyes had established themselves as co-rulers in Transcaucasia (*c.* 630 B.C.). In 589 Saulius reigned over the Royal Scyths. His brother Anacharsis (whose existence is doubted by certain authorities) went to Greece as his ambassador and became so much respected there that the Greeks spoke of him as "the Scythian eloquence." The throne then passed to Idanthyrsus who, with his brothers Taxacis and Scopasia, expelled Darius. Ariapeithes, the son of Idanthyrsus, came to the throne next, marrying in turn a Greek woman, a Scythian, and a daughter of a Thracian chieftain. He was succeeded by his son Scyles, who was murdered shortly before the time of Herodotus by his brother Ostomasades because of his fondness for Greek manners, dress, and religious observances. The murderer succeeded his victim on the throne. His successor, Arianthus, is remarkable for having organized a census of his people. The next known ruler, Aristagorus, reigned *c.* 495 B.C. A descendant, Ateas, was killed in 339 B.C. at the age of 90 while fighting against Philip II of Macedonia. King Agarus' reign likewise ended with his death in battle (310 B.C.). Nothing is known of the kings who followed him till Scylurus established himself in 110 B.C. at Neapolis (in the Crimea) and struck Scythia's first coins at Olbia. He was succeeded by his son Palakus, the last Scythian sovereign whose name has been preserved in history.

Hippocrates described the Scythians as inclined to laziness, fatness, and gaiety, likening their appearance to that of eunuchs and commenting on their sexual impotence; but his statement is corroborated neither by the events in their history nor by the appearance of those Scythians whose features have been preserved on contemporary Greek metalworks—for example, on the electrum kumiss jug from the Chertomlyk burial.

Administration Under the Royal Scyths.—For administrative purposes the Royal Scyths divided their kingdom into four districts, each of which was controlled by a governor provided with a paid military bodyguard. The governor dispensed justice and levied taxes from the settlers and tribute from certain of the Greek Pontic cities. The tribal way of life remained in force; communities were governed by their elders or chieftains, these dignitaries being periodically summoned to attend a general assembly held in the presence either of the governor or of the sovereign. These assemblies differed from the gatherings held by the sovereign in the spring of each year in order to inspect and feast his army. In times of war the country was divided for purposes of recruitment into three sections, the enrolled men being later grouped into units, each one of which was commanded by its own officer.

The Army.—The army consisted entirely of freemen, *i.e.*, Scythian tribesmen; they were fed and clothed but paid no wage, though those of them who could produce the head of a soldier killed in battle were entitled to share in the day's booty. According to Herodotus, the Scythians scalped their victims, fashioning their skulls into cups which they wore attached to their belts, using them to pledge an oath in a mixture of blood and water. Such cups mounted in delicately worked gold have been found in several tombs.

Many Royal Scyths wore bronze helmets and chain-mail jerkins of the Greek type lined with red felt. Their shields were generally round and made of leather or iron, often decorated with a central gold ornament in the form of an animal, but other tribesmen carried square or rectangular shields made of wood or leather. All used a double curved bow, shooting over the horse's left shoulder; arrows had trefoil-shaped heads made, according to date, of bronze, iron, or bone. Arrows and bow were carried in a gorytus (bow case) slung from the left side of the belt. Their swords were generally of the Persian type, with a heart-shaped or triangular crosspiece intricately ornamented. According to date, the blades were of bronze or iron; in southern Russia, the sheaths were often encased in gold worked into embossed designs and offset with paste or ivory inlay and gems. Their knives were of various shapes and lengths, some being curved in the Chinese manner. They wore the dagger attached to the left leg by straps, and many carried spears or standards surmounted by bronze sculptures depicting real or imaginary beasts.

Horses.—Every Scythian owned at least one gelding to serve as a riding horse, but the wealthy possessed a great many mounts; most Scythians also owned oxen or rough ponies, which served as beasts of burden. The finest riding horses were of the Fergana breed, but the majority were Mongolian ponies. The Scythians devoted much time and attention to their horses and ornamented all their trappings. Bridles were provided with metal cheekpieces in the shape of animals, and the leather straps were adorned with embossed, cutout, or appliqué designs, which also often represented animals. Saddles consisted of two felt cushions mounted on wooden frames bound with yellow or red and sometimes embellished with gold plaques; the felt saddle cloths were adorned, as were the seats of the saddles, with appliqué designs. Metal stirrups were not known to the Scythians, but there is reason to believe that they rested their feet in felt or leather supports. Women lived in subservience and semiseclusion, traveling with their children in covered wagons with solid wheels and a central shaft along which mules or oxen could be yoked in pairs.

Possessions.—The frozen tombs of Pazyryk (*see* below, *Tombs*) contained many well-preserved articles of clothing, all of which were profusely trimmed with complicated embroidered and appliqué designs; the clothes of the wealthy in southern Russia were covered with tiny gold-embossed plaques, sewn to the garments. At Pazyryk felt appliqué wall hangings were found, some displaying religious scenes featuring the Great Goddess or anthropomorphic beasts, others with geometric or animal motifs. Even the embalmed body of a man was covered with tattooed designs of real and mythical beasts executed with great spirit and delicacy. Felt rugs were found, as well as a knotted, woolen pile carpet of Persian origin, from the 5th century B.C., displaying figures of riders, elks, and stars. Felt cushions and mattresses, wooden tables with carved or turned legs and detachable, slightly hollowed, traylike tops, and wooden blocks serving as stools or head rests were customary.

SCYTHIAN SETTLEMENTS AND BURIAL GROUNDS. INSET MAP SHOWS AREA OF HIGHEST CONCENTRATION IN AND NEAR THE CRIMEAN PENINSULA (TAURIC CHERSONESE), SOUTH RUSSIA

The tombs of the Eurasian plain as a whole produced a mass of tools and domestic utensils, many of them made of precious materials. Rich jewelry and arms of great value and beauty are frequently found in the burials belonging to the western section. In addition, each burial throughout the entire area contained a cast bronze cauldron of the distinctive Scythian shape. These cauldrons vary in size from quite small examples to others weighing as much as 75 lb.; an overwhelming majority have a solid base, shaped like a truncated cone, round which the fire was heaped. The upper section is a semispherical bowl provided not with a loop handle but with handles (shaped like animals) fixed to the rim opposite each other. The finest cauldron, found at Chertomlyk in the Dnieper district, has six handles. At Pazyryk, small cauldrons filled with stones and hempseeds were found standing beneath leather or felt tentlets with three or six supports. Herodotus referred to what he termed a Scythian purification rite which, he noted, consisted in inhaling the fumes of hempseeds thrown onto hot stones; the passage was well-nigh incomprehensible till archaeologists discovered that a smoking outfit of this sort had been provided for each person buried at Pazyryk, making it clear that hemp fumes were inhaled for pleasure and not, as Herodotus assumed, as part of a religious observance.

Occupations and Beliefs.—The Scythians were keen huntsmen and fishermen; they were skilled at curing hides; they excelled at working metals; and the settlers were good agriculturalists. Though they had neither an alphabet nor, until later times, a coinage, they carried on a lively trade not only with the inhabitants of central Asia but also with the Greeks of the Pontic cities, often exchanging surplus goods and furs for Greek luxuries such as fine ceramic wares.

The Scythians worshiped the elements but they were not a devout people and never felt the need for temples. Their deepest feelings were centred on the Great Goddess, Tabiti-Hestia, the patroness of fire and beasts, and she alone of all their deities figures in art. They also worshiped Papeus-Zeus, god of the air; Apia-Gaea, goddess of the earth; Oetosyrus-Apollo, god of the sun; Artimpaasa-Aphrodite, goddess of the moon; Thamunasades-Poseidon, god of water; and, in time of war, possibly also Ares and Heracles. They do not appear to have had any priests, but they had a class of magicians and soothsayers, the Enaries, who spoke in high-pitched voices and dressed as women. The Scythians believed that these feminine characteristics had been inflicted upon them by the Great Goddess as a punishment for desecrating her shrine at Ascalon; they were probably eunuchs and may well have been the men Hippocrates had in mind when describing the appearance of the Scythians.

Burial Customs.—The Scythians venerated the graves of their ancestors, sparing neither wealth nor labour in providing vast tombs richly furnished and equipped. Their funerary rite was elaborate and as costly in lives as in material. In the Altai, interment took place only in the spring and autumn weeks, and embalming was therefore essential. The Scythians of southern Russia also resorted to it, adopting the process Herodotus ascribed to them. Once the corpse had been prepared, it was customarily placed on a cart. Then the mourners (in the case of a chieftain, the entire tribe; for a lesser person, the family and friends), having cropped their hair, wailing and tearing their clothes, would conduct the dead man during 40 days through the lands that had once belonged to him or, if he had none, would escort him on visits to his relatives and friends.

On the 40th day the body was carried to the tomb and, while one of the dead man's wives, his principal servants such as his cupbearer and groom, and a substantial number of his riding horses were being put to death, his body was lowered into the main burial chamber; the dead man's newly killed companions and servants were then laid in the graves which had been prepared for them. The bodies of the horses were also placed within the mound, the tombs of the Scythian and kindred nomads all taking the form of horse burials.

All the dead wore their finest jewelry and clothes and the best of their arms and accoutrements, and they also took with them the objects considered necessary for their future life, only the best of their possessions being chosen for the tomb. The horses were harnessed in their finest trappings; at Pazyryk some were even provided with elaborate masks made of felt and leather touched up with gold, some in the shape of a stag's head, complete with antlers, some surmounted with figures of birds. The number of horses varied with the period and the region, in some cases running into hundreds.

Finally, according to Herodotus, the Scythians marked the first anniversary of a chieftain's death by choosing 50 men from his bodyguard, all of them freeborn tribesmen, and putting them to death, together with their mounts; the men were then seated on their horses and the bodies impaled together on stakes set in a circle round the tomb, so that the faithful dead might forevermore guard it from desecration. It is unfortunate that this method of protection, so costly in human and animal lives, failed to achieve its purpose; almost every Scythian grave opened by archaeologists has been found to have been rifled in antiquity.

Tombs.—Tombs of the Scythian and kindred tribes are found from the Altai to eastern Europe. In the Altai the method of construction sometimes led to the formation of a layer of ice above the grave and to the preservation of the tomb contents as efficiently as in a modern deepfreeze. As a result, many of the materials that perished in the western burials have been preserved in the Asiatic tombs. The frozen burials of Pazyryk date from the 5th to the 3rd century B.C. There the size of the mounds is measured by their circumference rather than by their height, for all are low, being topped only with a covering of boulders. It was this boulder cover that caused the formation of a layer of ice when the rainwater that seeped through it to the earth filling beneath became frozen. The richest Scythian tombs are situated in the Soviet Union, primarily in the Kuban region and in the kingdom of the Royal Scyths (*i.e.*, on the Dnieper and in the Panticapaeum

region in the eastern Crimea), though poorer burials are found over a much larger area. The tombs of the chieftains are extremely elaborate constructions, the larger having as many as five chambers, each measuring some 9 ft. by 15 ft. and 7 ft. in height; they often lie as much as 40 ft. below virgin soil, while the mounds erected on them vary from 400 to 1,200 ft. in diameter.

In southern Russia, at a chieftain's death a sloping trench was first dug; at its further extremity a shaft was sunk into virgin soil to form the main burial chamber; subsidiary graves, as many as five in number, were prepared for the chieftain's companions. Next the trench had to be transformed into a corridor and then the graves had to be made to resemble the rooms or tents in which the dead had spent their terrestrial existence. This was accomplished by smoothing the sides of the excavated areas and facing them, according to the region, with tree trunks, matting, birch bark, thatch, or even fabrics. In the Crimea painted decorations were often preferred, while at Pazyryk wall hangings were customary. Hooks were fixed into the walls and spare clothing hung on them; shelves were built round the sides to hold provisions. The ceilings of the subsidiary graves were treated in much the same manner as the walls, but four posts were often sunk into the main grave to support either a canopy placed above the corpse or a roof; floors were often covered with gravel or rushes. The dead were orientated toward the east, laid on mattresses, often set on biers; in the Altai, however, the bodies were laid in coffins made of hollowed-out tree trunks.

In southern Russia the chieftain's body occupied the main chamber; his wife's was placed in the next best; and his retainers were laid in the others, the grooms always being given preferential treatment. No special graves were provided for the horses, their bodies being laid round the tomb in as orderly a manner as possible; but when a large number of horses were sacrificed the corpses were often piled one upon the other in a heap. At Pazyryk, on the other hand, the horses were ordinarily buried in a separate but adjoining chamber decorated in much the same manner as the section of the tomb reserved for the chieftain and his companions.

BY COURTESY OF THE HERMITAGE, LENINGRAD

ARTIFACTS OF SCYTHIAN CIVILIZATION

(Top) Gold stag plaque, probably central ornament from a shield; 6th century B.C. Found at Kostromskaya Stanitsa. (Bottom left) Gold comb with ornament showing battle between Scythians; 5th–4th century B.C. Found at Solokha. (Bottom right) Horse's burial mask of felt, leather, gilded hair, and copper in shape of stag's head; 5th century B.C. Found at Pazyryk

In Hungary the burials of Zöldhalompuszta and Tápiószentmárton are among the most important because of the magnificent gold plaques in the shape of stags found there; in eastern Germany that of Vettersfeld is of particular interest on account of the gold figure of a fish of remarkable design discovered in it, together with interesting items of military equipment.

Art.—Nothing that has so far been found in the Altai has proved of the same intrinsic value as the objects discovered in the western burials, but they show that similar work was produced by the artists of the entire Eurasian area, whether they worked in wood, leather, bone, appliqué felts, and coarser metals such as bronze and iron or whether they used more precious materials such as silver, gold, or electrum. The artists and craftsmen of the Scythian age were fascinated by the animals they saw or imagined, and though numerous objects were decorated with geometric forms, many of them symbolic or magical, the art of the period is essentially an animal art. Combat scenes between two or more animals are numerous, as are single animal figures. Many real or mythical beasts are represented, the majority of the types having roots in deep antiquity, but the Scythians fashioned them in a manner that was new and characteristically their own. As is to be expected with nomads who were constantly on the move, the objects they produced are generally small in size, but many are made of precious materials and practically all are of superb workmanship.

The gold figures of semirecumbent stags, measuring some 12 in. in length, are outstanding; they were probably used as the central ornaments for the round shields carried by many Royal Scythian fighters. In pre-Scythian times the stag was used as a totem by the tribesmen of Siberia, but in the Scythian period the emblem had lost much of its religious significance. Perhaps the loveliest of the gold stags is the 6th-century-B.C. example from the burial of Kostromskaya Stanitsa in the Kuban, but versions of the 5th century B.C. from Tápiószentmárton in Hungary and of the 4th century B.C. from Kul Oba in the Crimea are scarcely less beautiful. Certain scholars ascribe the former to Thracian and the latter to Ionian craftsmen, yet all conform wholly to Eurasian traditions, and much more concrete evidence is necessary before the former of these attributions can be accepted as final. In the three the stag is shown in a recumbent position, with its legs tucked beneath its body, but with its head raised and its muscles taut so that it gives an impression of rapid motion. The stag also figures prominently in the art of the Pazyryk people, whether as leather or felt cutouts or as carved wooden terminals.

The Scythians' artistic idiom is one of great compression as well as of synthesis; contrasting positions of the body are combined with astonishing skill to depict every possible aspect of the animal when visualized during all its diverse activities, zoomorphic junctures of fabulous intricacy helping to evoke the animal kingdom in its abundant multiformity. Thus, though the art is basically representational in character, it is at the same time impressionist in spirit, while it also often verges on the abstract in conception; yet, however complex its elements, they are fused in the finished work into a single entity of compelling force and beauty.

SCYTHOPOLIS: *see* BEISAN.

SEA ANEMONE, a sedentary and usually solitary marine animal whose flowerlike appearance is striking; the name anemone is taken from the Greek word for windflowers. Sea anemones are polyplike coelenterates belonging to the class Anthozoa (*q.v.*). The

radial arrangement of the usually colourful tentacles around the disc that bears the mouth at its centre is reminiscent of the petals of a flower.

Anemones vary in size from polyps only a fraction of an inch in both length and diameter to giants measuring about three feet in diameter. These carnivorous animals are common along all of the sea shores of the world, abundant in bays and estuaries, and occur even in the greatest depths of the oceans; they are never found in fresh waters. Most anemones adhere tenaciously by their bases to hard substrates such as rocks, other animals, pilings, wharves, and ship bottoms. They seldom move, although a slow creeping motion is possible. Some anemones do not possess a base, but have instead a specialized aboral region, the physa, which makes it possible for them to burrow into soft muddy or sandy bottoms, where they will be found with just their tentacles and oral area exposed. A few anemones with a base, such as *Stomphia* and *Boloceroides*, can release their grip upon the substrate and by movements of the column or tentacles can swim short distances. *Minyas* has a base that secretes a porous, chitinous mass that serves as a float in carrying the anemone about at the surface of the water. Anemones are devoid of a skeleton but they may secrete a horny cuticular covering or, by using various adhesive structures on the body wall, cover themselves with sand grains, bits of shell, or other foreign objects.

FIG. 1.—GENERAL FEATURES OF A SEA ANEMONE

Many sea anemones possess unicellular algae in their tissues; these algae, while not serving directly as food, are a source of organic material that leaks from their cells and contributes to the nutrition of the host anemone. Anemones possess stinging cells, or nematocysts, on their tentacles, which makes it possible for them to capture other animals. Symbiotic relations exist between anemones and other animals. Certain crabs carry sea anemones about in their claws, and some hermit crabs bear sea anemones upon their borrowed shells. The anemones, with their nematocysts, presumably serve as protection for their mates in these associations.

Technically sea anemones may be classified into several groups: (1) Actiniaria, or true sea anemones, are the solitary burrowing, attached, or free floating animals; (2) Ptychodactiaria, or deep water anemones, are found in the Arctic and Antarctic; (3) Corallimorpharia are solitary or tropical forms intermediate between corals (Madreporaria) and sea anemones (Actiniaria); (4) Zoanthidea are solitary or colonial anemones, many species of which occur on the stalks of sponges, sea fans, and sea feathers; (5) Ceriantharia are solitary types that live in tubes formed of mucus and extruded nematocysts. These animals usually occur in soft bottoms in subtidal locations.

SEABORG, GLENN THEODORE (1912–), U.S. physical chemist and co-winner with Edwin M. McMillan of the 1951 Nobel prize in chemistry, is known principally for his work on the synthetic transuranium elements. He was born in Ishpeming, Mich., on April 19, 1912, and was educated at the University of California (A.B., Los Angeles, 1934; Ph.D., Berkeley, 1937). He was successively research associate, instructor and assistant professor (1937–45), becoming professor of chemistry and associate director of the Radiation laboratory in 1945. He served as chancellor, 1958–61.

With his co-workers, he added (1940–55) eight new elements encompassing atomic numbers 94–101, of which plutonium (94) is the best known because of its use as a nuclear explosive and for nuclear power. During World War II, which he spent as a section chief at The University of Chicago metallurgical laboratory, the first industrial production of plutonium was undertaken in the newly devised uranium reactors, and Seaborg had the primary responsibility for isolating the plutonium from the reaction products. The other new elements were: americium (95), curium (96), berkelium (97), californium (98), einsteinium (99), fermium (100), mendelevium (101). Following the tentative identification of nobelium (102) in Sweden in 1957, he predicted, at the Geneva conference on atomic energy (1958), the possible discovery of six more synthetic elements. In Jan. 1961 President Kennedy named him chairman of the Atomic Energy commission. (I. P.)

SEABURY, SAMUEL (1729–1796), American clergyman, first bishop of the Protestant Episcopal Church in the United States, was born in Groton, Conn., on Nov. 30, 1729. After graduating from Yale in 1748, he served for four years as catechist in Huntington, N.Y. In 1752 he went to Great Britain and, after studying medicine for a year at Edinburgh, was ordained deacon and priest successively on Dec. 21 and 23, 1753. Returning to America, he served as rector in New Brunswick, N.J. (1754–56); Jamaica, N.Y. (1757–66); and Westchester, N.Y. (1766–75). He took a loyalist stand in the Revolution and wrote some pamphlets on that side under the pseudonym of A. W[estchester]. Farmer. These led to his being arrested by the revolutionary party and held prisoner in Connecticut for several weeks. After his release, he returned to Westchester for a while but later sought refuge with the British forces in New York, where he served for a time as chaplain of a loyalist regiment. He was there at the end of the war when the clergy of Connecticut, meeting in Woodbury on March 25, 1783, made him their second choice for bishop. As Jeremiah Leeming, the first choice, declined, Seabury was sent to England to seek consecration. A special act of parliament was required to permit the consecration of American bishops, and various circumstances connected with Seabury's election made the archbishops hesitate to seek the power in his case. He then went to Scotland, where he secured consecration on Nov. 14, 1784, from bishops of the nonjuring Episcopal Church in that country. In the meantime, Episcopalians in the middle and southern states had begun a movement that led to the adoption of a constitution for the church in 1786 and the consecration of two bishops in England in 1787. Between that event and the next meeting of the General convention in 1789, the leaders of the church were concerned with the problem of uniting the two episcopal lines. The difficulties arose from Seabury's political views and from uncertainty as to the canonical status of the Episcopal Church in Scot-

land. A conciliatory spirit finally prevailed on both sides, and the whole Protestant Episcopal Church was united in the second session of the General convention of 1789. A third bishop was consecrated in England, and all four bishops joined in the consecration of Thomas John Claggett as bishop of Maryland on Sept. 17, 1792, the first consecration on American soil. Though disappointed in some features of the church's constitution and of the Book of Common Prayer as revised in 1789, Seabury secured their acceptance in Connecticut, where he continued to serve as bishop and as rector of the church in New London until his death on Feb. 25, 1796.

See also PROTESTANT EPISCOPAL CHURCH.

SEA COW, an aquatic mammal of the order Sirenia (*q.v.*) but in a restricted sense the recently extinct Steller's sea cow (*Hydrodamalis stelleri*). This gigantic relative of the manatee and dugong (*qq.v.*) formerly inhabited Bering and Copper islands in the Bering Strait near Kamchatka. It was discovered in 1741 and described by Georg W. Steller, who accompanied Vitus Bering in his voyage of exploration. It was killed in large numbers by Russian sealers and fur hunters, who found the animals easy to hunt; by 1768, less than 30 years after its discovery, the sea cow apparently was exterminated.

The sea cow reached a length of about 24 ft., with a relatively small head and broad, horizontal, forked tail fluke. The thin skin was dark brown in colour, sometimes streaked or spotted with white. The jaws were toothless but provided with ridged horny plates. The flippers were short and blunt, lacking the terminal joints of the digits. When discovered, these sirenians were numerous in bays, where they browsed upon the abundant seaweed. Bones of the sea cow are still found there from time to time. (J. E. HL.)

SEA CUCUMBER, popular name, after their shape, for warty-skinned marine animals of the class Holothurioidea, the most aberrant and diversified class of the Echinodermata (*q.v.*).

RUSS KINNE-PHOTO RESEARCHERS INC.

SEA CUCUMBER (CUCUMARIA FRONDOSA) PHOTOGRAPHED OFF THE COAST OF MAINE

The body is usually elongate, often sausage-shaped, with a spacious body cavity, or coelom, and well-developed muscles that enable the holothurians to move in wormlike fashion. In size, sea cucumbers range from about an inch (order Elasipoda) to several feet (order Apoda) in length. They are usually dull in colour, being shades of gray, drab, brown, and black; however, some are brightly coloured. The skeleton is usually reduced to minute spicules, important for classification; rarely, larger plates are present, and a few forms presumably have lost all spicules. The water vascular system, characteristic of all echinoderms, is well developed in some orders and almost nonexistent in others. Food is collected by means of tentacles, modified tube feet that surround the mouth. In the bizarre primitive deepwater forms, the Elasipoda, the tentacles are hardly more than enlarged tube feet by means of which the animals scoop up the ooze of the sea bottom. In more advanced groups, the tentacles may become shovellike organs, as in the many reef forms of the tropics, or they become richly branched and are used as a net in which plankton particles are strained and afterward transferred to the mouth, where the tentacle is licked clean. In the streamlined members of the order Molpadonia, which tunnel their way through mud, the tentacles are small and used as digging tools, while at the same time food is taken in. The wormlike Apoda, which burrow, use their tentacles in the same manner, while forms that live on reefs have large feathery or plumose tentacles that sweep up food particles. The Holothurioidea comprise about 500 species, ranging from extreme shallow water to the greatest depths of the ocean. A few are utilized as food (*see* BÊCHE-DE-MER). (EL. D.)

SEAFORD, an urban district and seaside resort in the Lewes parliamentary division of East Sussex, Eng., 4 mi. SE from Newhaven by road. Pop. (1961) 11,021. The town is sheltered by the South downs behind and the high chalk cliff of Seaford head to the east. In former days the Ouse entered the English Channel there, and the natural harbour so formed accounts for the origin of Seaford, probably in Roman times, though it is not mentioned in Domesday. It became a corporate limb of the Cinque Port of Hastings, and was doubtless of considerable importance until about the end of the 14th century, when its rapid decline began as a result of the silting up of the harbour and the increase in the size of ships. In the 16th century the town was finally deserted by the Ouse, which now runs into the sea at Newhaven, and no revival of its prosperity occurred until the early 19th century, when it began to be frequented as a seaside town. Seaford is noted for the number of schools established there. The beach is pebbly though there are sands at low tide.

SEAHAM, a seaport and urban district in the Houghton-le-Spring parliamentary division of Durham, Eng., 5 mi. SSE of Sunderland by road. Pop. (1961) 25,889. Seaham is mentioned in a document of 930, but modern Seaham dates only from 1828, when the 3rd marquess of Londonderry built a harbour for the export of coal from the Rainton pits. Later the three Seaham pits were sunk.

The district was first known as Seaham Harbour and comprised Seaham and Dawdon, but in 1937 New Seaham was incorporated and the name changed to Seaham.

SEA HORSE, a small marine fish whose horselike appearance in the head and arched neck has long provided a motif in art. Sea horses belong to the genus *Hippocampus*. Like other members of the pipefish family (Syngnathidae), they have the body enclosed in bony rings, the tiny mouth at the end of a tubular bony snout, the gills lobate, the pelvic fins lacking, the anal fin minute, and the dorsal fin serving as the organ of locomotion by means of wavelike rippling. They differ from typical pipefishes in the heavier build, in carrying the head at right angles to the body, in lacking the caudal fin, and in the more extreme development of the tail end of the body into a prehensile appendage. As in the pipefishes, the female deposits the eggs in a pouch under the tail of the male, who then broods the young until they hatch. About 50 species, ranging from an inch or two to nearly a foot in length, inhabit warm seas. Sea horses are sold as dried curios, and are sometimes kept in aquariums.

SEA ISLANDS. These low-lying islands form a chain off the coast of South Carolina, Georgia and Florida between the Santee and St. Johns rivers. The more important islands are Folly, Edisto, Hunting, Parris, Port Royal and St. Helena off South Carolina; Tybee, Wassaw, Ossabaw, St. Catherines, Sapelo, St. Simons, Jekyll and Cumberland off Georgia; and Amelia off Florida. A number of wildlife refuges and parks have been established on the islands and some are popular resorts. The first Europeans who were to claim the Sea Islands and partly to occupy some of them were the Spaniards, who established Roman Catholic missions on most.

By the end of the 17th century the Spaniards had been driven off the islands north of Florida and early in the 18th century the English laid claim to them, making them a part of the colony of Carolina. An aura of romance and speculation enveloped the islands for more than two and a half centuries, beginning in 1717 when they were granted to a Sir Robert Montgomery, who made them a part of his margravate of Azilia on the mainland, and called them the Golden Islands in a promotional booklet he issued in 1720. Sir Robert's scheme met with failure, and when Georgia became a colony in 1732 and settlement began the next year, the islands were among the first parts of the colony to be occupied. The battle of Bloody Marsh fought on St. Simons in 1742 saved the colony from destruction by the Spaniards. These islands were early looked upon as private little kingdoms. St. Catherines was awarded to Mary Musgrove, a half-breed Indian princess, in payment of a debt claimed against James Oglethorpe, the principal founder of the colony; and before the end of the colonial period the island came into the possession of Button Gwinnett, one of Georgia's three signers of the Declaration of Independence. Rice and cotton plantations were established, especially on the South Carolina islands of St. Helena and Port Royal and the fine, long-stapled Sea Island cotton was developed. After the American Civil War, abandoned plantations were confiscated and the land was given to freed slaves; the population of the Sea Islands of South Carolina still is predominately Negro. (*See* also PORT ROYAL; GULLAH.)

In the 20th century, in part because of boll weevil infestation of the cotton, a more diversified agriculture developed, including corn, peanuts, potatoes, poultry and truck gardening, and Sea Island shrimp, crab and oysters were harvested in quantity. A U.S. marine corps training installation is located on Parris Island.

Of the Islands off Georgia, almost all of Sapelo in the antebellum period became the domain of Thomas Spalding, prominent Georgia slaveholder, planter and legislator; in the second half of the 20th century it remained in private hands. In the last half of the 19th century Jekyll was made an exclusive winter playground for members of the Jekyll Island club; and the Carnegie family secured most of Cumberland about the same time for the same purpose.

The state of Georgia bought Jekyll from the club and since 1947 it has been a state park. Fort Frederica national monument, established 1945, is on St. Simons which with adjoining Sea Island also has resort facilities. Jekyll, St. Simons and Sea Island are near Brunswick (*q.v.*). The Florida Sea Island, Amelia, was first settled by Oglethorpe in 1735. It became part of East Florida, Spanish, in 1783 and was ceded to the United States with the rest of Florida in 1821. The northern part of the island is occupied by a state park.

See E. M. Coulter (ed.), *Georgia's Disputed Ruins* (1937); E. M. Coulter, *Thomas Spalding of Sapelo* (1940); B. Vanstory, *Georgia's Land of the Golden Isles* (1956). (E. M. Co.)

SEAL, an aquatic mammal of the family Phocidae, suborder Pinnipedia, order Carnivora (*see* CARNIVORE). The phocids are the true seals; the eared seals, comprising the fur seals and sea lions (including the trained seals of the circus), belong to the family Otariidae (*see* SEA LION). The body is torpedo-shaped. The limbs are short, with the fingers of the forelimbs joined to form a flipper bearing separate claws, and the hind limb with the toes joined by a web. In swimming, the body is propelled by side-to-side strokes of the paddlelike hind flippers, each flipper acting alternately in the power stroke. On land, progress is laborious, the body being hitched forward by the forelimbs and pushed along by the pelvic region alternately in a looping movement.

The seal differs from the sea lion chiefly in its mode of swimming, its gait on land and its lack of external ears. There are about 18 kinds of seal, those of temperate and polar seas being more numerous than those of the tropics; one species is confined to fresh water. Seals range in size from the little fresh-water seal (*Pusa sibirica*) of Lake Baikal in south Siberia, about 3 ft. long, to the enormous sea elephant or elephant seal (*q.v.*) of the subantarctic regions, the bulls of which reach a length of 16 to 18 ft.

Nearly all seals are gregarious, at least when breeding; some kinds assemble in enormous herds on sea beaches or floating sea ice. In species such as the elephant seal and gray seal (*Halichoerus grypus*) the males take possession of harems of cows and drive rival bulls away from their territory. One young at a time is normally born to each adult cow and suckled for a comparatively short while; the pups gain weight very rapidly on the diet of seal milk, which contains about 50% fat. During the period of suckling the cow remains ashore and does not feed. The newborn pups are clothed in a coat of soft, silky fur, which is molted about the time of weaning and replaced by coarser hair. In some species, such as the common or harbour seal (*Phoca vitulina*) and the sea leopard or leopard seal (*Hydrurga leptonyx*), the first molt is precocious and may take place partly or completely before birth. The fluffy birth coat is generally white but sometimes, as in the elephant seal, it is black. The cows are again impregnated soon after the birth of the pups. The gestation period is thus about 11 months or a little more; some species (possibly all) exhibit delayed implantation, in which the growth of the embryo is arrested at a very early stage and renewed some months later, so that active gestation may actually occupy only about seven months.

Seals appear to be long-lived, with a potential span of 30 or 40 years, but their average life in the wild is considerably shorter because of heavy mortality from accident and misadventure among the younger animals. Some kinds of seal, such as the common seal, inhabit coastal waters, but others, like the harp seal (*Pagophilus groenlandicus*) of the Arctic, the Weddell seal (*Leptonychotes weddelli*) and the crabeater seal (*Lobodon carcinophagus*) of the Antarctic, live in the open sea (*i.e.*, are pelagic) and generally leave the water only to lie on floating sea ice. The coastal species are more or less sedentary, but the pelagic ones make extensive, regular migrations. Seals produce a variety of sounds from the wailing bleat of the pup through snarls and barks to the windy roars of the elephant seal. The food of many kinds of seals consists mainly of fish; some species consume large quantities of squid, other mollusks, and crustaceans. The crabeater seal lives on planktonic crustaceans that it strains from sea water through the sieve formed by the serrated cusps of its side teeth. The leopard seal of the antarctic feeds largely on penguins and other sea birds.

Seals have a thick layer of blubber under their skin and some of the gregarious species are killed in large numbers by man for the sake of the oil that can be rendered from it. Their hides are sometimes used for leather, and the skins of newborn phocids in their fluffy natal coat are prized in the fur trade. *See* SEALING; *see* also references under "Seal" in the Index. (L. H. M.)

SEA LAW: *see* MARITIME LAW.

SEA LILY, the popular name for marine animals whose adult sedentary stage, stalked and flowerlike, suggests a lily; these forms belong to the Crinoidea, a class of echinoderms that includes also the stalkless feather stars. Sea lilies occur in deeper water, often in large numbers. Only about 80 species are present today, most under 2 ft. in height, while in earlier geological periods thousands of species, some of giant size (up to 70 ft. high), existed. The remains of extinct sea lilies preserve well and are important as guide fossils.

A typical sea lily has a tall, slender stem, composed of small, five-lobed calcareous discs and a small cup-shaped body, rigid with plates, with the mouth and anus placed on the upper, soft-skinned side. From the edge of the cup arise, in the simplest forms, five articulated arms with alternating rows of shorter branches, the pinnulae. In most forms the arms fork near the base so that a multiple of the original five arms is developed. The animals feed on microscopic particles carried to the mouth along ciliated grooves present on the upper side of the arms and pinnulae. The water vascular system is well developed; the podia, which fringe the arms are delicate cylindrical types that, besides serving sensory and respiratory functions, assist in collecting food. (El. D.)

SEALING is the taking of certain genera of seals for their fur, hides, blubber or oil. Most commercial sealing is conducted on land or on ice at the breeding grounds, or rookeries, particularly those in the north Pacific and north Atlantic. For many years the taking of seals was accompanied by great waste with the result that the seal herds were threatened with extinction, but sealing in most areas is now regulated by international conventions or other agreements that aim at conserving the breeding stock. Pelagic sealing, *i.e.*, the taking of seals in the open sea while the animals are migrating to the breeding grounds, was once practised indiscriminately in the north Pacific but is now prohibited because it was especially wasteful. As a general rule, regulated sealing is conducted so as to harvest only the superfluous males.

Commercial sealing is now conducted mainly in the Pribilof Islands (*q.v.*) of the north Pacific, on pack ice in the northeast and northwest Atlantic, and in rookeries of the South Pacific. The most important seals in the sealing industry are the fur seal in the north Pacific, the harp (Greenland) seal in the north Atlantic, and the elephant seal in the South Pacific. The ringed (jar) seal is also important. (*See* Seal.)

The North Atlantic.—Seals were first taken in the subarctic region of the north Atlantic by whalers when whaling began there early in the 17th century. Later, in the most prosperous days of north Atlantic whaling, the whalers neglected the seals but by the latter part of the 19th century they included them again in their catch. Sealing as a separate occupation had meanwhile developed in the north Atlantic during the 18th century. The chief species taken were the Greenland, harp or saddleback seal (*Pagophilus groenlandicus*), hooded or bladdernose seal (*Cystophora cristata*) and bearded or squareflipper seal (*Erignathus barbatus*).

The greatest annual kills in the north Atlantic took place off Newfoundland and in the Gulf of St. Lawrence between 1820 and 1860, when more than 500,000 seals were taken in several years. The largest annual kill on record is that of 1831, when 687,000 seals (mostly harp seals) were taken by about 300 ships and 10,000 men. After 1910, between 250,000 and 300,000 seals were taken annually, except during World War II, when most of the sealing ships were inactive.

The ringed, or jar, seal (*Pusa hispida*), the commonest and most widely found seal of the arctic, is one of the most important animals to the Eskimo. In some places it was and still is the backbone of the native economy. In the Canadian arctic between 30,000 and 50,000 seals are killed annually and the skins of about 10,000 of these animals are traded to the Hudson's Bay company each year. The skin of the one-year-old animal is particularly prized by fur dealers and is called the silver jar. The gray seal (*Halichoerus grypus*) and the common or harbour seal (*Phoca vitulina*) are not the subject of organized commercial exploitation. Both the gray seal and common seal, however, are killed by fishermen, in some places for a government bounty, because they are the primary hosts for certain parasites of commercial fish and because they are a nuisance around certain fishing operations.

Sealing in the north Atlantic is done in the spring on floating pack ice from the White sea to the Gulf of St. Lawrence. The chief species taken is the harp (Greenland) seal. There are three distinct breeding stocks, all of which are exploited commercially. An eastern stock breeds in the White sea (now a Soviet fishery exclusively), a central stock in the region of Jan Mayen island (U.S.S.R. and Norway) and a third off Labrador and Newfoundland and in the Gulf of St. Lawrence (Norway, Canada, U.S.S.R., U.S., Denmark and France). The species is strongly migratory; it occupies the pack ice area during the breeding season in the spring and then moves north to open water in the arctic in summer and autumn.

The white-coated pups, which are born on the ice, form the basis of the international Atlantic commercial seal fishery. Before World War II, almost 90% of the catch was of pups. Sealing in this area was primarily a Newfoundland industry. After 1949 the centre of the industry shifted to Nova Scotia.

In another post-World War II development, a Norwegian fleet of about 16 sealing vessels began to fish off Newfoundland and in the Gulf of St. Lawrence when their Soviet concessions in the White sea expired. About the same number of Canadian vessels were added to the northwest Atlantic sealing fleet at the same time. After these ships appeared, many older seals began to be taken until they finally constituted about 30% of the catch.

The pups are taken on the ice beginning early in March. Bedlamers (immature harp seals one year old or older) and adults are shot on the ice while molting during April and May. The pelts with their adherent blubber, called sculps, are removed on the ice and dragged or winched to the sealing ship; there they are stored in iced or refrigerated holds. The annual catch of harp seals in the 15 years following the end of World War II, including landsmen's net catches in Canada and Greenland, averaged about 225,000 pups and 85,000 immatures and adults, with about 90% of the catch shared equally by Canada and Norway. Sealers in both east and west areas of the north Atlantic used airplanes after World War II to locate herds.

Oil, fur and leather are the three major commodities produced from seals in the north Atlantic. The pup is the basis of the fur stock, though the short hair of the immatures is also used. Neither the pup nor the immature furnishes true fur and the value of their pelts is less than that of the true fur undercoat of the fur seal. The white coat of the pup consists of fetal hair that is replaced, beginning about 10 days after birth, by a short, spotted hair coat that grows in under the white coat. There were no formal laws in the early 1960s governing the killing of seals in international waters of the western Atlantic and the herd was being seriously reduced. In 1961 Canada proposed to the International Commission for Northwest Atlantic Fisheries (ICNAF) that the conservation of harp and hooded seals be placed under that organization. This was accepted by the commission and ratified by all member countries. Sealing in the eastern Atlantic was regulated by a Soviet-Norwegian treaty on arctic marine mammals.

The North Pacific.—The fur seals, which, with the sea lions, belong to the family of eared seals (Otariidae), differ from other seals in that they possess a permanent undercoating of short, soft fur that constitutes the sealskin of the costumer (*see* Sea Lion). The Pacific fur seal (*Callorhinus ursinus*) began to be exploited after V. J. Bering made his voyage to the north Pacific in 1741. The migrations of the fur seal cover the area from the latitude of southern Japan on the west and from southern California in the east to the great rookeries on the Komandorski (Commander) and Pribilof islands on the north. At their heights in the 19th century the Pribilof herd included about 2,500,000 seals and the Komandorski group totaled more than 1,000,000. A herd on Robben (Tyuleniy) Island in the Sea of Okhotsk was of minor importance. These herds were greatly reduced in the last half of the 19th century and by 1897 did not exceed a combined total of 600,000 animals. As a result of international treaties and control by the U.S. bureau of fisheries, the Pribilof herd increased from 125,000 in 1911 to about 1,000,000 in the second half of the 20th century.

Pelagic sealing in the north Pacific began in the early 19th century. At first the catch averaged 75,000 annually but after about 1868 it increased rapidly. Beginning in 1879, sailing vessels carrying canoes were employed to attack the migrating seals, which were thus harvested just before the breeding females gave birth to their pups; in some of the catches, half of the animals were pregnant females. At one time the pelagic sealing vessels exceeded 100 in number and some of them carried as many as 25

canoe crews. It has been estimated that by 1902 about 1,000,000 seals had been taken at sea.

The greatest catch, however, was always made on shore. From the Pribilof and Komandorski herds nearly 2,500,000 seals were taken on land between 1868 and 1897.

From a conservation standpoint it is fortunate that the habits of the seals on land permit their taking with the least possible depletion of the breeding stock. The young males, or bachelors, leave the rest of the herd to rest and sleep on beaches that are adjacent to but apart from the breeding grounds. There they are surrounded at night by the sealing crews, rounded up in droves of from 1,000 to 3,000 and driven inland to the killing grounds. The large droves are broken up into groups of from 20 to 50; the males three years of age or in that size class are knocked down with clubs, while those that are too large or too small are allowed to escape. The skins are removed, salted in kenches and, when cured, exported.

Many laws and treaties have been enacted to protect the north Pacific seals while they are at sea and thus to ensure a continued sealing industry. In 1911 an international convention was signed by Great Britain (for Canada), Japan, Russia and the United States to prevent pelagic sealing by their nationals. Land sealing also was regulated. At that time the herd on the Pribilofs numbered about 125,000 animals. The annual take there now runs between 50,000 and 70,000 skins, and the herd numbers well over 1,000,000 animals. The convention of 1911 was terminated in 1941 by the withdrawal of Japan. A provisional agreement between Canada and the United States ensured continued pelagic protection off North America. Then in 1957, Canada, Japan, the U.S.S.R. and the U.S. signed the Interim Convention on Conservation of North Pacific Fur Seals. This pact was to last six years, during which time commercial pelagic sealing continued to be prohibited, and an extensive pelagic and land research program on fur seals was undertaken by the four member countries to form the basis for negotiating a new convention. The North Pacific Fur Seal commission was set up by the four member countries to coordinate the work. At the end of the six-year period the time for research was extended. (*See* also ALASKA: *Diplomacy Involving Alaska;* WILDLIFE CONSERVATION: *Conservation of Sea Mammals and Fish: Seals.*)

The South Atlantic and Pacific.—The southern fur seal (*Arctocephalus australis*) was once taken at the Galapagos Islands, Tierra del Fuego and Lobos Islands. This or other species also were taken at South Africa, Australia, New Zealand and many points near the Antarctic circle. It was taken before 1793 and was once abundant in South Georgia and other dependencies of the Falkland Islands.

Great numbers of sea leopard or leopard seal (*Hydrurga leptonyx*), sea elephants or elephant seals (*Mirounga angustirostris* and *M. leonina*), Weddell seal (*Leptonychotes weddelli*) and other species were seen by early explorers and voyagers, but at first the skins of the fur seals alone seem to have been taken. One of the earliest recorded landings for seals is that of the Argentine ship "Juan Nepomucena," which brought in 13,000 skins in 1820. In that and the two following years more than 90 vessels, divided about equally between Great Britain and the United States, worked the southern grounds. In the first season, catches of 18,000 were not unusual for individual ships and five British ships took a combined total of 95,000 seals. Seal oil and blubber, particularly from the elephant seals, began to be taken. James Weddell estimated that in the two seasons of 1820–21 and 1821–22, 1,200,000 fur seals were taken from South Georgia and 320,000 from the South Shetlands, along with 940 tons of elephant seal oil. By 1892, because of the diminution of the herds, sealing vessels returned to their home ports from South America with mixed cargoes; and though in the early 1890s a Scottish whaling expedition to the Ross sea took 20,000 sealskins with four ships, by the end of the 19th century the fur seal had almost completely disappeared from the Falkland Island dependencies and other seals, sea elephants in particular, had greatly diminished in number.

From 1881 sealing in these territories has been regulated; closed seasons were introduced and sealing is now permitted only by licences, which may specify both the kind and number of seals taken. The capture of fur seals is prohibited.

Most sealing in the southern region is conducted in pursuit of the elephant seal; this sealing has responded satisfactorily to regulations. The elephant seal is taken by whalers, but pups may not be taken nor, as far as practicable, are female seals to be harvested. There is also a closed season and areas along certain stretches of coast are closed. The absence of segregation of young males on the rookeries is a hindrance to the observance of the regulations. Elephant seals are of great size, the females reaching 11½ ft. and the male sometimes 22 ft. in length. Mating takes place within the harem immediately after the young are born early in October, and the young, which are born singly, are usually weaned in November; these circumstances have determined the closed season. Shortly after mid-20th century, the number of seals taken at South Georgia was about 6,000 per annum.

SEALING WAX was once widely used to seal letters and attach impressions of seals to official documents. In medieval times it consisted first of a mixture of beeswax, Venice turpentine, and colouring matter, usually vermilion, but when lac from the East Indies was introduced into Europe by the Venetians it displaced the beeswax. Sealing wax was prepared by melting the rosin in a copper or earthenware pot and adding the colouring matter slowly while stirring. The molten mixture was poured into stick-shaped molds. In later times, sealing waxes containing admixtures of chalk (calcium carbonate), magnesium carbonate, and barite white (barium sulfate) and employing mineral pigments were developed. In very inferior waxes, ordinary rosin was substituted for lac.

Since the advent of the gummed envelope and various methods of affixing official seals, sealing wax has had only a few applications as a sealing material. It has been used with some success in decorative handwork. (E. L. Y.)

SEA LION, a name given generally to all members of the eared seal family (Otariidae), also called otaries; in a more restricted sense it is applied to the larger forms, such as the northern or Steller's sea lion (*Eumetopias jubata*), and to species of *Zalophus*, to which belongs the California sea lion (*Z. californianus*). Otaries, along with true seals (Phocidae) and walruses (Odobenidae) constitute a suborder of Carnivora (*see* CARNIVORE: *Seals and Seal Allies* [*Pinnipedia*]).

There are about 15 species of otaries, frequenting the North and South Pacific ocean, the South Atlantic and the southern oceans but entirely absent from the North Atlantic. One of the southern species extends up the west coast of South America as far as the Galápagos Islands. Some species of otary undertake regular and extensive annual migrations; those breeding on the islands of the North Pacific ocean journey as far as California every year. One of the smaller species, the California sea lion, is commonly kept in captivity and is the kind generally seen in circuses, trained to balance objects on its snout.

All otaries have a thick layer of blubber beneath the hairy skin and, though fur seals are principally valued for their pelts, the so-called "hair seals" are hunted for the oil obtainable from their blubber.

Otaries differ from true seals or phocids in having external ears

and a longer and more distinct neck, and in the formation of their limbs. The limbs, as in the true seals, are flippers with the digits joined, but the toes of otaries bear separate straplike extensions beyond the last joint. The locomotion of otaries is quite different from that of phocids. Their forelimbs are longer than those of phocids and their hindlimbs are long enough to be rotated forward under the body when the animal is on land. The body can thus be lifted clear of the ground; otaries can lope along at a clumsy gallop for a limited distance at considerable speed. In swimming, the body is propelled by powerful strokes of the forelimbs, whose effective area is increased by a fold of skin joining the trailing edge to the body wall; the hindlimbs, unlike those of the true seals, are of secondary importance in swimming.

Adult males and females differ greatly in size. The mature bulls in some species are more than twice as large as the cows and have an enormous development of the neck muscles and of the mane on the head and neck.

The Otariidae also includes the fur seals. These have a thick, soft fur beneath their coarse outer hair; the pelts of the young bulls and of the females form the seal fur of commerce. The wild herds are scientifically managed on their breeding grounds so that an annual crop of pelts is harvested without risking extermination of the animals—a possibility in former times, when indiscriminate slaughter was practised.

Various kinds of fur seals are found in both northern and southern subarctic and temperate seas. The northern fur seal (*Callorhinus ursinus*) ranges along the North American coast from Alaska to the Mexican border and breeds in the Pribilof Islands. The southern fur seals (*Arctocephalus* or *Arctophoca* species) range from sub-Antarctica to southern South America, Africa, Australia and New Zealand.

The voice of an otary is harsher than that of a phocid, and ranges from a sharp bark or honk to a growling roar. Otaries are strictly gregarious in the breeding season; some species gather on remote islands in herds numbering millions. They have a well-developed harem system, with the master bulls fiercely defending their territories and the younger, bachelor bulls gathering in segregated herds.

Otaries feed on squid and fishes. During their time ashore the bulls fast for several months; but the cows leave the beaches at intervals, presumably to feed, after their pups are born. The gestation period is about 10 or 11 months; but, as with true seals, there is probably a delay in implantation of the embryo.

(L. H. M.)

SEALS. The word "seal" (Latin *sigillum;* Old French *scel*) denotes the result of the impact of a hard engraved surface, the die or matrix, upon a softer material such as clay or wax, producing a device in relief, the impression, whereby from remote antiquity, as shown by cylinder seals from Babylonian sites, from Egypt, and from Crete, and later by the intaglio gems of classical Greece and Rome, the authenticity of documents was established in the manner of the modern written signature. The term "seal" is apt to be ambiguous, and in medieval times was sometimes used indifferently for the matrix or the impression; where there is doubt, it should be applied to the latter. For seals in antiquity *see* BABYLONIA AND ASSYRIA: *Art and Art Objects: Glyptic;* AEGEAN CIVILIZATION; CRETE: *Archaeology: Seals;* GEM.

EUROPEAN SEALS

After the fall of the Western Roman Empire in 476 the practice of sealing declined, and except that the popes, following a custom that originated with the Eastern emperors, used bullae (or lead seals) from the middle of the 7th century, and some very debased examples were used by the Visigoth and Merovingian kings, it was not revived in Western Europe until Carolingian times under Pepin the Short (d. 768). The seals then employed were either antique gems or contemporary derivatives: Charlemagne (d. 814) had a gem engraved with Jupiter Sarapis; later the German king and Holy Roman emperor Otto I the Great (d. 973) used a portrait bust of himself. In England the antique gem appeared on the counterseal of Durham Cathedral in the 10th century. Rock crystal was specially favoured, a conspicuous example being the crystal intaglio of Lothair II, king of Lorraine (d. 869), now set in a reliquary cross and preserved in the cathedral treasury at Aachen. Engraved gems were generally set in a metalwork mount on which the legend was engraved.

The earliest example of a "seal of majesty" with the monarch crowned and enthroned appears to be that of the emperor Otto III (d. 1002). In England there is no evidence of this before Edward the Confessor, after whom there is a continuous series down to modern times.

Before the end of the 11th century seals were used only by sovereigns, the higher clergy, and nobles, but by the end of the century sealing had become more general, and by the 13th century seals were used by craftsmen and tradesmen. While one seal would suffice for these, persons holding high rank would require more. The sovereign in addition to his great seal would have a privy or secret seal, a signet, generally a ring, and deputed seals for courts and officials, and various official seals of commerce. Bishops, like corporate bodies, had normally a seal of dignity, another *ad causas* (for current business), a private seal, and a signet. The lesser seals of persons who also possessed seals of office are known as "small seals."

The study of seals (sigillography) is important not only in the fields of genealogy and diplomatics but also in art history, particularly since most seals can be fairly closely dated. In Europe the evolution of style can be followed in miniature by this means. The late 12th century marks the beginning of the great period of seal engraving, which reached its zenith in the 13th and 14th centuries. The Renaissance brought a taste for opulent and intricate detail in the devices even in the heraldic shields, where perhaps it is shown at its best. About this time signet rings, often set with engraved gems, had their vogue. For the 17th century and later nonannular fob seals and desk seals are characteristic, surviving until modern times.

The Matrix.—For the use of engraved gems as seals, *see* GEM. The commonest materials were bronze or latten, but gold matrices are recorded as having been used by royal personages and many silver examples have survived in all categories. Other materials were lead, pewter, ivory, and occasionally jet. (In the case of bullae, where the impression itself was usually of lead, the matrix might be of steel or iron.)

Where seal and counterseal were of the same size, one matrix would be provided with pierced lugs, into which pegs on the other would be inserted, the impression being secured by a press. More usually, however, the matrix had one face, and was applied by means of a handle, a flange at the back, a ridge with a loop for attachment, or a hexagonal cone surmounted by a pierced trefoil with or without a loop at the top.

Sizes and shapes varied, the largest seals being generally, though not invariably, official, either secular or religious. Of the many possible shapes the most usual were the circular and the oval or pointed oval, the latter particularly appropriate for representing standing figures.

Engravers.—Research has revealed the names of many English seal engravers, and there are records from the 12th century; apparently the earliest extant example is the silver corporation seal of Exeter, signed by a certain Luke, perhaps about 1200. For official seals there is a fairly continuous record, containing such makers of royal seals as Walter de Ripa (first great seal of Henry III), Nicholas Hilliard (1547–1619), goldsmith and miniaturist (second great seal of Elizabeth I), Thomas Simon, the finest medalist and engraver of his time (seals of Cromwell and Charles II), and members of the Wyon family (active from George IV to Victoria). J. Roman (see *Bibliography,* below) quotes many names of French seal engravers, and some names of craftsmen from other European countries are given in W. Ewald, *Siegelkunde* (1914).

Seal Impressions.—Seal impressions are most commonly of wax—either of natural colour, or red, black, green, or brown. The majority of metal bullae are of lead, like the numerous surviving papal examples, but some sovereigns had bullae struck in silver or gold either as a mark of their own dignity or to confer special honour on the recipient of a charter.

Except in the case of metal bullae, where suspension has always been the rule, seals were applied directly to documents (*en placard*) in the earlier periods. In England suspended seals came into being in the 11th century; in France impression on the deed continued till the beginning of the 12th and intermittently until its revival toward the end of the 13th. Suspension was achieved by cutting a tongue along the bottom of the document, to which a single or double seal could be affixed, or by a slit in the bottom of the document through which a parchment strip could pass, the loose ends being joined by the seal. From about the end of the 12th century silk and woolen cords were used by the higher ranks for important documents. About the end of the medieval period attachment *en placard* again became general.

The Counterseal.—The larger of the suspended seals normally bore a counterseal on the back for greater security, either the reverse of a double seal, or a secret seal, a signet, or an *ad causas* seal.

Devices and Legends.—The face of the majority of seals shows a central device with a surrounding inscription or legend commonly indicating the person or institution entitled to the seal, although on small private seals it may be a secular motto or a devotional sentiment. Latin appears at all periods, but English and French are found from the 13th century, sometimes along with Latin.

The word *sigillum* precedes the owner's name and description in the genitive case, but for royal seals the nominative without *sigillum* is used, as also on the earlier medieval bishops' seals of dignity. Abbreviations, owing to limited space, are common, and signs by way of punctuation usually separate the words. The types of lettering are, in very roughly chronological order, Roman capitals, Lombardic, black letter, and in post-medieval times Roman capitals again.

Types of Seals

Secular.—*Royal Seals.*—The earliest and most complete series is that of the French kings, where evolution can be followed from Carolingian times, the grand series of round seals with an enthroned figure of the king beginning with Henry I (d. 1060). In England the first royal seal which ranks as a "great seal" is that of Edward the Confessor, impressions of which are still extant. The seal was furnished with a counterseal, the design being nearly identical with that of the obverse. William the Conqueror, as duke of Normandy, used an equestrian seal, representing him mounted and armed for battle. After the conquest of England, he added a seal of majesty, copied from the seal of Henry I of France, as a counterseal. In subsequent reigns the order of the two seals was reversed, the seal of majesty becoming the obverse, and the reverse being the equestrian seal, a pattern that has continued to modern times. In the later Middle Ages royal seals became increasingly elaborate and a climax of magnificence was reached in the seal of Henry V of England (d. 1422).

Other Categories.—Interesting and important officers' seals are those of the admirals, extant examples being of value in showing the evolution of the ship in medieval and later periods. Commerce and industry are illustrated by seals used for customs, seals relating to the delivery of wool and hides, and cloth-subsidy seals. Unofficial commercial seals are exemplified by the seals of the livery companies and companies trading abroad. On many seals of private traders the device or the legend may indicate the occupation. Local seals comprise those of countries, towns, and their officials, various devices being found, sometimes the place itself. Castles are common, being a feature of English sheriffs' seals; some seals show bridges, while others may have a religious subject or merely a shield of arms. An exceptional class is the English series for labourers' passes under the Statute of Cambridge, 1388.

Universities show the chancellor and masters in convocation, while the colleges have patron saints or founders, a religious emblem as a shield of arms; the faculties and nations generally had seals, a common design being a doctor or master lecturing.

Religious Seals.—*Episcopal.*—The characteristic medieval seals of dignity from about the 11th century show the bishop blessing, robed and mitred and holding a crozier. As time went on, changes in vestments appeared and elaboration in the form of canopies, flanking figures, and tabernacle-work, giving place later to scriptural subjects or often to groups of saints, with the bishop in adoration at the base, with or without a shield of arms.

Monastic Seals.—Much the same evolution is seen in monastic seals, where the device is often appropriate to or illustrative of the institution. Armorial bearings are a common feature, whether subordinate to the principal subject or, later, the sole device. An exceptional group are the greater seals of the bishops of Durham as lords palatine with the enthroned figure on one face and the bishop as an armed knight on the other.

Some fine examples are found, in which the device is a building, probably that indicated by the legend; the splendid seals of Boxgrove Priory, Sussex, and Haltemprice Priory in the East Riding of Yorkshire are conspicuous examples.

Papal Seals.—Papal bullae form a class of their own. On the obverse are the heads of SS. Peter and Paul, and on the reverse the pope's name. Archaic from the beginning, they have so continued, in spite of attempts by Paul II to alter and by Julius II to improve the design.

REVERSE (ABOVE) AND OBVERSE (BELOW) OF THE SEAL OF WILLIAM I (THE CONQUEROR) WHO REIGNED 1066–87: REVERSE SHOWS THE KING ENTHRONED; OBVERSE SHOWS HIM FULLY MOUNTED AND ARMED

Personal Seals.—With private and personal seals a division falls naturally between heraldic and nonheraldic. The earliest type was the equestrian, showing the mounted owner fully armed, which began in the 11th century. From the second quarter of the 12th century, these seals show armorials and are valuable illustration of the changes in arms and armour; their best period is the late 13th and early 14th centuries. The purely armorial seal dates from the late 12th century; on it the shield is the sole or principal device, as in many of the categories of official commercial seals. Private seals probably appear about the end of the 13th century, usually small and circular; the succeeding centuries show increased elaboration of the means of filling the field, until in the 15th and 16th centuries the full armorial achievement is developed.

BY COURTESY OF THE BIBLIOTHEQUE NATIONALE, PARIS

SEAL OF THE UNIVERSITY OF PARIS, 1292: VIRGIN AND CHILD ENTHRONED (TOP CENTRE) SURROUNDED BY A BISHOP AT LEFT, STUDENTS READING BELOW, AND SAINT AT RIGHT

The seals of persons not entitled to arms show a great variety of devices, conspicuous among which are merchants' marks. Some bear their owner's name round fleurs-de-lis crescents, stars, and various conventional designs; others have legends describing the seal or expressing sentiments. Animal figures are also found on some seals, with relevant legends. (A. B. To.)

Small Seals.—Small seals supplemented the great seal. They were not duplicates of it nor, although in an emergency they could be used in its stead, were they intended to be substitutes. For instance, a late medieval bishop, with a seal *ad causas* for the administration of his diocese, would use a signet (sometimes called a seal *ad arma*) for personal correspondence and secular business; he might occasionally use this signet as a counterseal. Although originally designed for the private purposes of their owners, some small seals acquired an official character. Most medieval sovereigns had at least two small seals, which were placed in the custody of certain officials. Except in England, they were invariably controlled by chancery, as for example, in the papacy and in France. (*See* CHANCELLOR: *France*.) The English small seals' freedom from such direction allowed them to evolve autonomous offices which gave rise to some of the chief ministries of state.

Like some other developments in royal administration, the first small seal known to have been used in England dates from the reign of King John. This was the privy seal kept by the clerks of the king's chamber (*q.v.*) for use in business relating to the king's domestic economy. When the wardrobe assumed responsibility for such matters in the reign of Henry III, the privy seal was transferred to this department, and under Edward I and Edward II the controller of the wardrobe had charge of it. Although chancery at first enrolled writs of privy seal, the wardrobe itself recorded these writs in registers in the reigns of Edward I and his son. Many drafts of privy seal letters, originally kept in files, remain from this period.

As a result of the action of the ordainers in 1311, the privy seal was removed from the wardrobe and entrusted to its own keeper; the succession of keepers of the privy seal can be traced from 1312. The keeper became one of the foremost officers of state, ranking after the chancellor and treasurer. Except for the tenure of Nicholas Carew (1371–77), the seal was kept by clerks who usually received bishoprics in recognition of this service. The title lord privy seal first appeared when the office was held by Richard Foxe (1487–1516). Since 1530 the title has been held by laymen, who until recent years were usually peers.

The records of the privy seal office continued to be kept in files in the 15th century. Despite misfortunes, many have survived, some being published under the title of *Proceedings and Ordinances of the Privy Council of England* (ed. by Sir N. H. Nicolas, 1834–37). This mistaken description arose from the frequent notices on these records of activity by the king's council. As the council did not possess a seal or keep its own registers of proceedings until the 16th century, the privy seal office acted as the council's secretariat. It remained, however, a major instrument of the medieval king's personal government. Thousands of writs of privy seal which were sent into chancery to authorize the chancellor to issue letters under the great seal survive to this day, and many others are to be found in the records of the exchequer and other departments which required such writs before expenditure could be incurred. From drafts and formularies it can be observed that the privy seal was used for royal letters sent to foreign monarchs and to officers and subjects in England as well as those overseas. One important function of the privy seal office was the preparation of contracts for military service to the crown; the privy seal was attached to the part of the indenture kept by the king's retainer.

A number of royal seals smaller than the privy seal appeared during the 14th century. Edward II and Edward III had each in their early years a secret seal kept by their chamber clerks. Edward III also had small seals known as the *signum*, the novel signet and a griffin signet (the last for the administration of chamber lands). These seals were all short-lived, and a second small seal did not attain a significant position in the royal administration until the reign of Richard II. The rise of the signet and of the office of its keeper, the secretary, was due to the loss of royal control over the privy seal, which had attracted the attention of the baronial opposition. Although royal control was not lost permanently, the established position and multifarious activities of the privy seal office now demanded that it should have a fixed headquarters: the keeper rented an inn in London and the seal "went out of court." From time to time, however, the keeper was required to attend the sovereign on his journeys, and the privy seal long retained a great advantage over the signet in that it was well known and accepted without question. From 1418 to 1421, when Henry V was in France, there were two privy seal matrices, one with the king, the other with the council in England.

The uncertain standing of the signet was revealed in the reign of Henry VI. The king did not have a signet, or a secretary, in

England until he came of age in 1436, and in his periods of incapacity they ceased to be employed. Under Edward IV, however, the signet office was so securely established that it survived during the brief reign of his young son, Edward V. The earliest surviving register of the signet office dates from this time (1483). The monarch now tended to prefer to employ the signet to make the royal will known. The secretary supplanted the keeper of the privy seal as the king's attendant secretarial officer, and also took over his leading part in the management of relations with foreign powers. The activities of the privy seal office became increasingly formal, consisting largely of the issue of letters ordered by warrants under the signet.

Until 1533 the office of secretary was held by a clerk whose personal standing was not particularly prominent, but Thomas Cromwell, the first layman to hold the office, achieved such power that after his fall in 1540 Henry VIII appointed two secretaries. Cromwell was the first secretary of state in the modern sense, and from his time the office has followed its own line of development. The secretary detached himself from the signet office, which also became a purely formal department, issuing letters when required to do so by warrants under the royal sign manual. Up to the 19th century, the signet and privy seal offices were merely links in the bureaucratic chain whereby grants by the sovereign were ultimately made effective by letters patent under the great seal in chancery. The signet office was abolished in 1851 and the privy seal office in 1884. The lord keeper was retained and is now a member of the cabinet while there are seven secretaries of state who still each receive three seals from the sovereign at the time of their appointment and use the second of these (the lesser signet) for all government business requiring the sanction of an official seal. (R. L. S.)

SEAL OF THE UNITED STATES

When the United States came into existence the use of seals to authenticate important state documents was the prevailing practice, and the matter of obtaining a suitable seal was one of the first to which attention was given; on July 4, 1776, within a few hours after agreeing to the Declaration of Independence, the Continental Congress named a committee of three, Benjamin Franklin, John Adams, and Thomas Jefferson, "to bring in a device for a seal for the United States of America." There were, however, many delays; the report of this committee was tabled and two further committees were appointed before a decision was reached, on June 20, 1782.

The design in the report then accepted incorporated the suggestions of a number of people, but those primarily responsible were William Barton of Philadelphia, who had some knowledge of heraldry, and Charles Thomson, also from Philadelphia, the secretary of the Congress.

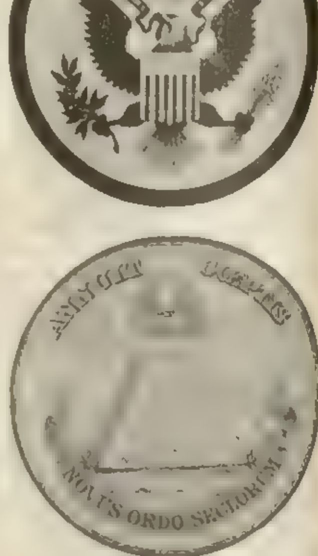
The description or blazon, which reads as follows, remains part of the law of the land today:

ARMS. Paleways of thirteen pieces, argent and gules; a chief, azure; the escutcheon on the breast of the American eagle displayed proper, holding in his dexter talon an olive branch, and in his sinister a bundle of thirteen arrows, all proper, and in his beak a scroll, inscribed with the motto, *"E Pluribus Unum."*

For the CREST. Over the head of the eagle, which appears above the escutcheon, a glory, or, breaking through a cloud, proper, and surrounding thirteen stars, forming a constellation, argent, on an azure field.

REVERSE. A pyramid unfinished. In the zenith, an eye in a triangle, surrounded with a glory proper. Over the eye these words, *"Annuit Cœptis."* On the base of the pyramid the numerical letters MDCCLXXVI. And underneath the following motto, *"Novus Ordo Seclorum."*

Soon after the action of Congress the obverse of the seal was cut in brass and was used as early as Sept. 16, 1782, on a full power issued to General Washington to arrange with the British for exchange of prisoners of war. By the act of Congress of Sept. 15, 1789, which changed the Department of Foreign Affairs to the Department of State, the seal of 1782 was declared to be the seal of the United States and the secretary of state was made its custodian.



OBVERSE (ABOVE) AND REVERSE (BELOW) OF THE GREAT SEAL OF THE UNITED STATES

In the course of its history six (or possibly seven) dies of the seal of the United States have been cut and used officially. The first, executed in brass, was employed as early as Sept. 16, 1782, and as late as April 24, 1841. This seal measures about $2\frac{1}{4}$ in. (6 cm.) in diameter. Its distinguishing characteristics are a border resembling a chain of flowers, six-pointed stars and the arrows touching the border. Intended for impression on wax, it had only one face, cut in intaglio. Almost invariably it was impressed on a circular paper wafer, a thin layer of red wax being introduced between the wafer and the document for the double purpose of attaching the wafer and bringing out the device in relief. The second die was cut in 1825. About $4\frac{1}{2}$ in. (11 cm.) in diameter, it depicts the eagle realistically rather than heraldically. This die did not supersede the first, but was employed concurrently with it, being reserved for preparing pendant seals.

The third die, which superseded the first, was used from April 1841 until November 1877. Of approximately the same size as the seal of 1782, it differs in the style of its execution. The device has the appearance of being crowded toward the top; the stars, which for the first time are five-pointed, are minute; and the sheaf of arrows departs from the law in that it includes not thirteen, but six. During the first twenty years or more of its service, this die, like that of 1782, was impressed on a wafer over wax; thereafter glue or paste replaced the wax for attaching the wafer to the document, and there are indications that a crude counter-die may have been provided. The die that superseded the third was used from November 1877 until April 1885. Measuring about 2¼ in. (6 cm.) in diameter, it was executed in close imitation of the seal of 1841; and like that seal it departs from the law in having only six arrows in the sinister talon. It is readily distinguished from the earlier seal by the larger size of its stars; and it was provided with a counter-die.

Criticism of the faulty design of the seal then in use led to an act of Congress of July 7, 1884, appropriating $1,000 to "enable the Secretary of State to obtain dies of the obverse and reverse of the seal of the United States, and the appliances necessary for making impressions from and for the preservation of the same." The design of the obverse was an enlargement of the seal of 1782 with modifications aimed at artistic improvement and stricter adherence to the original resolution creating the seal. Although the act of 1884 provided also for cutting the reverse, it was decided to leave this provision unexecuted; and the reverse of the seal, "spiritless, prosaic, heavy, and inappropriate," has remained uncut and unused to this day. Its diameter of 3 in. (8 cm.) distinguishes the die of 1885 from all previous dies. Provided with a counter-die, it was usually impressed over a paper wafer pasted to the document; but there are examples of its impression directly upon a document, a practice authorized by act of Congress of May 31, 1854. About 1888 the present style of wafer, with invected edge, replaced the serrated form previously used.

In 1903 a new die was engraved in hardened steel, following exactly the design of the seal of 1885. This die was first used on Jan. 27, 1904, and continues in current service. Measuring 3 in. (8 cm.) in diameter, it may be distinguished from the seal of 1885 by its greater depth and by minute differences in the rays of the "glory." In the 1885 seal all the rays are solid lines; in the 1904 seal every other ray is a dotted line. Like the earlier seal, it is provided with a counter-die; and it is usually impressed over a paper wafer pasted to the document, although examples are to be found without the wafer.

Legally, the seal has two designations, "the Great Seal" and "the Seal of the United States," both of which appear in acts of Congress and in a decision of the Supreme Court and both of which are in general use.

It has a limited use which is strictly guarded by law. With the expanding functions of the government, the extent of its use has been curtailed from time to time by act of Congress or executive order. For instance, where formerly the seal was affixed to all civil (not military or naval) commissions signed by the president, now persons appointed by the president to serve under Cabinet officers other than the secretary of state are commissioned under the seals of the respective departments. Except for some proclamations and the commissions of some civil officers, the seal is now used only in connection with international affairs.

Apart from the seal, and as the emblem or coat of arms of the nation, the device of the obverse is employed officially in innumerable ways, and sometimes in more or less modified form, for purposes of decoration or identification. It appears on medals, on stationery, on publications, on currency, on flags, in paintings, and as architectural adornments; it forms part of the seal of the Department of State and, with differences, part of the seal of the president; and it is displayed in colour over the entrance of embassies and other foreign service installations.

The symbolism of the obverse of the Great Seal is conventional and well known: the American bald eagle; the motto *"E Pluribus Unum"* ("One from many"); the olive branch of peace and the arrows of war; and symbols of the 13 colonies. That of the reverse is less familiar. The design incorporates the date of the founding of the nation, 1776; an unfinished pyramid, suggesting the firm and durable building of the new nation, not complete, however, and having room for other states; a single eye surrounded by the sun's rays, suggesting the eye of providence surrounded by the light of the universe; and two mottoes, *"Annuit Coeptis"* ("He [*i.e.,* God] has favoured our undertakings") and *"Novus Ordo Seclorum"* ("A new order of the ages"), both adapted from Virgil.

The states also have and use seals; for illustrations of these *see* UNITED STATES (OF AMERICA): *Administration and Social Conditions: State Governments.* (R. S. PA.; X.)

CHINESE AND JAPANESE SEALS

The use of seals for impressing personal names, ranks, and titles of office has existed in China since earliest times, and was introduced into Korea and Japan as soon as they came under the influence of Chinese culture. In China bronze seals have survived from the 5th century B.C., and even when allowance is made for the Chinese habit of attributing later practices to ancient, even legendary, rulers, the mention of seals in literature suggests that their use began earlier. The first strictly datable mention relates to the year 544 B.C., when a messenger carried to Duke Hsiang of the

state of Lu a "sealed document" (*hsi shu*). The Han Chiu I, a work on the organization of government by Wei Hung (1st century A.D.), records some regulations for official seals: those of the feudal princes were to be known as *hsi* and those of other nobles as *yin*, and both were to be of gold; the seals of ministers or generals, also of gold, were to be called *chang* and those of officials with a stipend of 2,000 piculs of grain or more to be known as *chang* and made of silver. There is no sign, however, that this distinction of terminology was ever closely observed, although it became customary to reserve the word *hsi* for imperial seals. In T'ang times *hsi* was replaced by *pao* in this sense. *Hsi* were traditionally large and square, made of jade, ivory, or precious metal and richly carved. The most famous imperial seal (now known only from the histories) was that of Shih Huang Ti, the first emperor of the house of Ch'in and unifier of the empire. It was made of fine jade with a knob in the form of a one-horned dragon, and bore the inscription:—"The Emperor glorious and long-lived, the recipient of Heaven's command." It is said to have been handed down the line of the succeeding emperors of the house of Han. A bronze seal of historical interest was found in 1784 in Fukuoka Prefecture, Kyushu, Jap. It reads "King of the Han Wei-nu country." The Later Han history records the arrival of Japanese tribute-bearers at the Chinese court possessing seals which had been accorded by the Han emperor Kuang-wu (A.D. 25–57), of which this is presumed to be an example.

The use of seals by private persons as a signature and a mark of possession on books, documents, paintings, and calligraphies survives to the present time. As a signature the seal generally bears the surname and personal name followed by the word *yin* (seal impression) set in square or oblong shape, and reading top to bottom and right to left, although this direction varies. Every Chinese who might be called on to sign his name in the past possessed and often carried such a seal. The seal (the word is used for both the die and the imprint) might represent the characters of the name in solid line or reserved against a background of the ink. The latter is always red. Even from the Han period the custom was to use a special form of characters—the *chuan* or seal script—which shows considerable deviations from the normal hand.

But besides signature seals, persons of literary and artistic pretensions had made for themselves ornamental seals, sometimes round, oval, or gourd-shaped, in which they recorded the name of their study or library, their own literary pseudonyms and sobriquets, words of commendation for the paintings, etc., on which the seals were impressed. Artists frequently had scores of such seals, to the inconvenience of art historians and the convenience of fakers. For although a signature seal might pass as a legal identification, subject to verification, seals could be counterfeited as readily as brush-written signatures forged, and some authorities would maintain that the authenticity of a painting can never rest merely on the evidence of seals.

The carving of inscriptions on seals, even in jade, became a refined hobby; and new seals might be commissioned or presented on any auspicious occasion. One famous example, familiar to students of painting, is the seal adopted by the great collector Emperor Ch'ien-lung on his birthday, which was impressed on many of the paintings in the imperial collection (now in the National Palace Museum, Peking).

SEAMANSHIP, the art of handling a ship or boat under any and all conditions of weather, tide, current, or other influence affecting its movement or safety. The term is also applied to the skill attributed to a good seaman. It should not be confused with navigation nor with pilotage (*qq.v.*), but it is a companion art to these; for without good seamanship in the actual maneuvering of the ship, good practical results cannot be achieved by the navigator or pilot.

In elementary form, seamanship is involved in the handling of even the smallest floating craft. In sailing ships, seamanship is largely concerned with rigging (*q.v.*), the making and shortening of sail (*q.v.*), and the correct manipulation of sails and rudder (*q.v.*) for maneuvering the ship. In power-driven ships, ability to maneuver the vessel by means of screw propeller and rudder replaces skill in handling sails. However, in the handling of all vessels it is necessary for the seaman to know the effect on the ship of wind, tide, and current; the behaviour of a vessel in a seaway; the various methods of anchoring in a harbour or mooring to a dock; the safety precautions required aboard ship; and the nautical rules of the road (*see* Rules of the Road at Sea).

Seamanship also involves a multitude of other services incidental to maritime work such as the proper loading of cargoes; shifting of weights; making the ship snug for heavy weather; handling the ship's boats; care of passengers; attention to the ship's fittings; and knotting and care of ropes.

Good seamanship is acquired by practice and natural aptitude. It cannot be taught by precept or the study of books alone. (M. H. I.)

SEAMI MOTOKIYO: *see* Zeami (Seami) Motokiyo.

SEA PEOPLES, a modern collective name for groups of aggressive seafarers who appeared in the eastern Mediterranean toward the end of the Bronze Age, especially in the 13th century B.C. The Sea Peoples are held responsible for the destruction of old powers such as the Hittite Empire. Their activities were but one aspect of major migrations of peoples which violently interrupted the old order elsewhere; *e.g.,* in Greece where the Mycenaean civilization was destroyed. The precise extent and the origin of the upheavals were still uncertain in the 1960s. The difficulty lies in the abrupt halt of historical sources (near eastern ancient archives) as a result of the invasions and destructions. Principal but one-sided evidence for the Sea Peoples comes from Egyptian texts and illustrations recording the successful defense of Egypt against the new enemies. Additional information can be gathered from Hittite sources, from archaeological data, and by comparison with later historical material (*see* Hittites). Recently, the archives of the north Syrian city of Ugarit (modern Ras Shamra) and new finds of tablets from the Hittite capital (Boğasköy) have added dramatic details concerning coastal raids and the final naval battles around Cyprus shortly after 1200 B.C.

The Egyptians waged two wars in which the Sea Peoples were involved. The Egyptian king Merneptah (*c.* 1236–1223 B.C.) in the fifth year of his rule defeated a Libyan attack from the west. The Libyans were supported by peoples called "northerners from all lands" whose names can be transcribed as Ekwesh, Teresh, Luka, Sherden, and Shekelesh. These five allies must have crossed the Mediterranean by ship to join the Libyans, and thus were

naval powers of some, if modest, importance. The second encounter of Egyptians and Sea Peoples took place under the rule of Ramses III (*c.* 1195–1164 B.C.) who faced major invasions in his fifth and his eighth year after the Hittite Empire and the Syrian coast had been devastated by the onslaught of "foreign countries" who started the troubles "in their islands." The attacks came by sea and by land, and the listing on this occasion is: Peleset, Tjeker, Shekelesh, Denyen, and Weshesh (*see* EGYPT: *History: New Empire: 20th Dynasty*).

Tentative identifications of the Sea Peoples are as follows:

Ekwesh: a group of Bronze Age Greeks (Achaeans [*q.v.*]; Ahhiyawa in Hittite texts).

Teresh: Tyrrhenians (Tursenoi) known to later Greeks as sailors and pirates from Asia Minor, ancestors of the Italian Etruscans (*see* ETRUSCANS: *Origins*).

Luka: a coastal people of western Asia Minor, also known from Hittite sources. They are known to have raided the coast of Cyprus (Alashiya) in the 14th century B.C. The name survives in classical Lycia on the southwest coast of Anatolia.

Sherden: Sardinians to judge by their name and appearance. The Sherden acted as mercenaries of the Egyptians in the battle of Kadesh (*c.* 1299 B.C.) where Ramses II fought the Hittite king Muwatallis. In this land battle the Hittites had the Luka among their allies. In Egyptian illustrations the Sherden wear helmets with horns and carry swords and round shields, equipment similar to that of bronze warrior figurines found on Sardinia.

Shekelesh: The name suggests that this tribe is identical with the Sicilian tribe called Siculi (*q.v.*).

Peleset: generally admitted to refer to the Philistines (*q.v.*) who settled in Palestine after their defeat in Egypt. In the reliefs of Ramses III's funeral temple at Medinet Habu, the Philistine (Purasati, Pulesati) sailors are shown wearing stiff crowns (often called feather crowns, but perhaps a special haircut combined with diadem and chinstrap). The same headgear is apparent in terracotta images on sarcophagi from Beth-shan (Beisan) and on seal impressions from Enkomi on Cyprus; in both cases, contact with Philistines or Sea Peoples is clear. The Philistines after their arrival in Palestine made a decorated kind of pottery which is of Aegean derivation; their connections with Crete are archaeologically probable.

Further identifications (Tjeker-Teukroi; Denyen-Danuna or Danaoi) are much more uncertain.

The problems connected with the Sea Peoples concern their provenance and the chronology of their migrations. It is not known if any of them came from the western Mediterranean before the attacks on Egypt (*e.g.*, the Sardinians and Sicilians, who certainly lived in the west later). The extent to which the Aegean islands were responsible for the unrest is uncertain. The Trojan War can be seen as a prelude to the Sea Peoples' raids in the eastern Mediterranean, and both Ekwesh and Philistines have Aegean connections. The Luka and Teresh can be interpreted as Anatolian peoples; for the others, there hardly seems room along the known shores of the eastern Mediterranean. The coming of iron into the ancient world may be connected with the Sea Peoples, in which case part of their strength may have derived from eastern Asia Minor, perhaps the Black Sea coast.

SEAPLANE, an airplane capable of taking off from and landing on water; depending upon its design, it is also sometimes referred to as a flying boat, float plane or hydroplane. The first practical seaplanes were built and flown in the United States by Glenn H. Curtiss in 1911 and 1912. For the next 30 years they played an important role in the development of aviation.

The Curtiss inventions led swiftly to the famous British F-boats of World War I, which originated such naval missions as over-ocean reconnaissance and patrol, aerial antisubmarine warfare and mine laying, and air-sea rescue. After the war, commercial versions of the same seaplanes set the range and endurance records of the time, and inaugurated the first international airlines from the U.S. to Cuba and Canada. In 1919, the U.S. navy's water-based NC-4 conquered the North Atlantic. In 1924 four single-engine landplanes of the U.S. army were converted to water operation and made the first flight around the world.

In the 1930s, the largest and fastest aircraft in the world were seaplanes. Their utility and versatility were dramatized by a Russian flight from Moscow to New York via Siberia, by Gen. Italo Balbo's mass flights from Rome to Rio de Janeiro and Chicago, Ill., by Col. Charles A. Lindbergh's flights over the Pacific, and by Adm. Richard E. Byrd's extensive mapping of Antarctica—all with marine aircraft. Seaplanes were used by the German airline, Deutsche Lufthansa, for transcontinental and ship-to-shore airmail service, and by the U.S. Pan-American Airways to initiate regular transpacific and transatlantic service. The "China clipper" became one of the most famous types flown across the Pacific ocean. Racing seaplanes held the absolute speed record from 1931 to 1939, and many of their advanced features were later incorporated in the famous British fighter planes of the early 1940s.

After the outbreak of World War II, the military and commercial significance of seaplanes gradually diminished, partly because of the construction of land bases and aircraft carriers. Following World War II, the development of water-based aircraft continued on a small scale in Great Britain and the U.S., but major advances in aeronautics of this era were made with land-based equipment.

Characteristics and Types.—A seaplane must have sufficient buoyancy to float on water and must also have some means for supporting its weight while moving along the water surface at speeds up to flying speeds. It must be able to take off and land with a margin of stability and control on the part of the pilot; its structure must be strong enough to withstand the shock of landing; and its water resistance must be low enough to permit reasonably short take-off runs.

Ways of meeting these requirements were provided by Curtiss in the form of float seaplanes which are essentially landplanes with buoyant floats or pontoons substituted for the landing wheels, and flying boats in which the main floats and fuselage are combined in a single boatlike body. Single float seaplanes and single hull flying boats require side floats or wing-tip floats to keep them upright. Twin float seaplanes do not require the auxiliary floats, nor do twin hull flying boats and single hull boats with stub wings or sponsons located at the water line.

The addition of a retractable wheel landing gear to a float seaplane or flying boat, also first accomplished by Curtiss, creates the amphibian aircraft capable of operating from land runways or water. A post-World War II development was the pantobase or all base airplane incorporating devices for operating from water or from a variety of unprepared surfaces such as snow, ice, mud and sod.

Performance.—When buoyant floats are added to an airplane in place of landing wheels, the plane's weight and aerodynamic drag are generally increased and its flight performance is impaired. These penalties also exist to a degree in smaller propeller-driven flying boats since the hull must be larger than a landplane fuselage to provide water clearance for propellers, wings and tail surfaces; but in larger sizes the apparent weight penalty may disappear because of a disproportionate increase in the weight and complexity of the landplane gear. The amphibian and pantobase airplanes naturally have additional weight penalties arising from their many different functions.

Jet propulsion promises the seaplane exemption from the size required for propeller clearance. It offers for the first time true size and performance parities with landplanes having similar wings and power plants. Nevertheless, flight performance penalties are crucial items in seaplane technology; traditionally they have been the subject of much scientific investigation on the part of aircraft manufacturers and aeronautical research laboratories.

Seaplane Research and Development.—With continual advances in power and flight speeds, aeronautics has been favoured by a concentration of scientific research effort never before known in the history of transport. In this effort, all known mathematical tools have been brought to bear, and the use of scale models for systematic experiments on the problems of flight has become a

sophisticated art. The seaplane, along with other aircraft, has benefited from this scientific climate, and its particular drawbacks have been the subject of considerable aerodynamic and hydrodynamic research, notably by such government laboratories as those of the National Advisory Committee for Aeronautics (N.A.C.A.) in the U.S., the Royal Aircraft Establishment (R.A.E.) in Great Britain, the Deutsche Versuchsanstalt für Luftfahrt (D.V.L.) in Germany, and the Guidonia aeronautical centre in Italy. These laboratories have provided staffs, wind tunnels and seaplane towing tank facilities for theoretical treatments of the fundamental phenomena involved, experimental verifications of the theories and evaluations of their applications to practical aircraft.

Model investigations of seaplane components and configurations were originally carried out in ship model testing establishments. In the 1920s and 1930s specialized towing tanks were built by D.V.L., N.A.C.A., R.A.E. and Guidonia with higher testing speeds for simulating seaplane operating conditions up to the minimum flight speeds of aircraft. These tanks were later augmented in the western world by high-speed facilities at the experimental towing tank of the Stevens Institute of Technology in the U.S., and by several private facilities operated by seaplane manufacturers in the U.S. and Great Britain.

As a result of hydrodynamic research of the post-World War II era, particularly in the U.S., where the department of the navy offered encouragement, important scientific progress was made in theories of planing surfaces, water impact loads and submerged lifting elements (hydrofoils). Better design methods were devised for achieving optimum proportions and shapes of flying boat hulls, improved take-off and landing qualities, and extended rough water capabilities in the face of increasingly severe military performance requirements. Because of limited actual procurement and operation of seaplanes, however, methods for water handling and beaching seaplanes at their terminals and at austere forward bases remained in a relatively primitive stage of development.

Hydro-skis.—Jet propulsion brought with it an improved design concept for water-based aircraft wherein the buoyant float system or oversized flying boat hull is dispensed with and fully retractable planing elements are provided for taking off and landing in much the same manner as with retractable wheels. With this concept, the seaplane floats at rest on the optimum fuselage for flight. The planing elements or hydro-skis are extended for water operation and retracted flush with the fuselage while in the air. Hydro-skis have proved to be compatible with advanced transonic and supersonic airframe and power plant arrangements. Because of their relatively small size and high loadings, they markedly reduce the loads and motions induced by wave impacts.

Land-Water Operations.—As a further extension of the hydro-ski principle, small landplanes have been operated off beaches and ramps on hydro-skis with no attempt to provide flotation at all. In this method of operation, pioneered by Canadian bush pilots with snow skis, the aircraft accelerates on land to the relatively low minimum planing speed of the skis; it then enters the water to complete its take-off run. On landing, the procedure is reversed and the airplane comes to rest conveniently out of the water. This novel means of operation requires runways or cleared areas only a few hundred feet long instead of the thousands of feet needed for conventional landplane operation.

Vertical Take-Off and Landing.—With aircraft designed to rise from and return to the earth vertically, the usual hydrodynamic requirements of water basing virtually disappear. Helicopters have been successfully converted to water operation simply by installing inflated rubber float systems for buoyancy and stability while afloat or by making the fuselage watertight and adding side floats for stability. A further development has been a helicopter fuselage shaped somewhat like a rudimentary flying boat hull for improved water taxiing characteristics.

Notable Seaplanes.—The largest seaplane built was the U.S. "Hughes Hercules" cargo transport flying boat, completed in the latter stages of World War II. This aircraft had a wing span of 310 ft., a gross weight of 400,000 lb. and was powered by eight 3,000-h.p. engines. Because of temporary wartime restrictions on aluminum, it was constructed entirely of molded plywood. The war ended before the plane actually went into service, but it demonstrated that seaplanes are not bound by the same size limitations as landplanes.

BY COURTESY OF U.S. NAVY

U.S. NAVY MARTIN P5M-2 "MARLIN"

Another notable seaplane was the "Mars" flying boat built by the Glenn L. Martin Co. In one short flight in 1949 a "Mars" carried more than 300 persons. A four-engine military transport, it had a wing span of 200 ft. and made regular flights from California to Hawaii.

The British continued the production of large propeller-driven flying boats in the post-World War II era. Their development culminated in the Saunders-Roe SR/45 "Princess" transport for luxury passenger service between London and New York. This aircraft had a pressurized hull for high-altitude operation, a gross weight of 300,000 lb. and was powered by ten turboprop engines of 3,000 h.p. each. It had a pay load capacity approaching 50,000 lb., a range of more than 4,000 nautical miles and a cruising speed of 300 knots at an average altitude of 30,000 ft. It was test flown in 1952, but was not placed in service because of withdrawal of government support. U.S. procurement in the same time period was entirely of naval seaplanes; there was no parallel commercial activity. The U.S. navy continued production of replacements for the World War II Martin PBM "Mariners" until 1949 and in the 1950s built more than 200 Martin P5M "Marlins", all-weather flying boats for service with the fleet. The "Marlins" were 72,000-lb. aircraft, driven by two 3,400-h.p. reciprocating engines and carried a large payload of electronic submarine detection equipment.

The first turboprop seaplanes in the United States were the Convair P5Y and R3Y "Tradewind" flying boats intended for naval patrol and logistic transport missions. The latter had a maximum gross weight of more than 170,000 lb. and a cruising speed exceeding 300 knots at an altitude of 25,000 ft. One version incorporated a bow-loading arrangement for movement of troops and equipment on and off beaches; another, multiple in-flight refueling equipment for carrier-based fighters.

The first turbojet seaplane was the British Saunders-Roe Sr/1A experimental water-based fighter, built and flown in 1947. It employed a conventional straight-wing flying boat arrangement with a single jet intake in the nose of the hull. The U.S. navy unveiled the XF2Y-1 "Sea Dart" developed by Convair in the early 1950s. The "Sea Dart" had a delta-wing transonic configuration with air intakes located above and behind the pilot's canopy. It represented the first literal application of the retractable hydro-ski principle. It was operated successfully with a twin ski system mounted on shock absorbing struts, and with a smaller single ski system mounted on fixed struts.

Conclusion.—Airplanes having thrust-weight ratios of less than one and capable of utilizing natural waterways as their runways have in the past been an effective answer to man's desire to move quickly at will about the earth. Many of their intrinsic advantages—superior economy, safety, flexibility of operation—un-

fortunately have been lost sight of by commercial and military interests. In the second half of the 20th century, they continue to offer to airline planners a practical means of alleviating growing problems of airport cost, congestion, noise and safety. Proponents of the seaplane contend that, for military use, they can provide invulnerable bases, dispersal of weapons systems, relief from undependable land-base arrangements with grasping or unstable governments and the safest test beds for gaining experience with nuclear propulsion away from inhabited areas.

SEA POWER. In its classical sense this term refers to all the means by which a nation extends its military power onto the seas. It is important both in peacetime and in wartime, for by its mere existence sea power affects a nation's influence in peacetime.

Sea power is sometimes confused with the possession of a large merchant marine, but a nation may have a considerable merchant marine without possessing notable sea power, as do Norway and Greece and as did the United States before 1860. Conversely, a nation may possess great military power upon the seas without boasting much of a merchant marine, as did the United States for the two decades preceding World War I. On the other hand, Great Britain was for centuries the world's leading naval power in the military sense and also possessed the world's largest merchant marine.

The main purpose of sea power has always been to protect friendly shipping from enemy attack and to destroy or hinder the enemy's shipping, whether that shipping was used for commercial or military purposes. In the time-honoured phrase, it has aimed at "using the sea for oneself and denying its use to the enemy." When one belligerent or the other has virtual control of surface shipping in portions of the seas, the situation has been traditionally known as "command of the sea." Attaining such command in the areas of chief importance has usually been the first aim of the naval antagonists. In a great naval war each side may command different areas of the sea, and each may try to extend its own area of command and to dispute the command in those areas claimed by the enemy. Large areas may be so generally in dispute as not to reflect a condition of command at all.

The strategic functions of sea power during wartime fall into five major categories:

1. Sea power protects the movement over water of one's own military forces and their supplies to coastal areas where they may be landed and used against enemy forces. This may mean landing an army on a hostile shore or on a friendly shore for operations in nearby territories.

2. It also protects from enemy attack the friendly shipping that carries the commodities of ordinary seaborne trade, including industrial goods and raw materials that support the nation's war economy.

3. It prevents the enemy from using the sea to transport his own military forces. It may thus constitute the primary means of defending one's homeland or overseas territories against enemy invasion.

4. Sea power may exert military and economic pressure on the enemy by preventing him from importing by sea commodities necessary for his prosecution of the war. It also prevents him from exporting products and thus obtaining funds to pay for military commodities received from neutrals to whom he does have access. It may exert pressure upon neutrals to prevent them from trading with the enemy. This use of sea power is known as blockade (*q.v.*) and has usually been exercised according to specific procedures prescribed by international law.

5. Naval forces have also been used to bombard land objectives from the sea. In the first half of the 20th century this function of sea power grew enormously in importance. The development of the aircraft carrier added a new dimension to this bombardment capability, as did the missile-firing nuclear submarine. In the early 1960s the nuclear submarine was on the way to becoming the single most important instrument of sea power; it was scarcely distinguishable in function from strategic air power in a general nuclear war.

The Instruments of Sea Power.—Sea power has never meant merely warships. It has always meant the sum total of the weapons, institutions, installations, and geographical circumstances that enable a nation to exercise military power at sea. The airplane used in the control of seaborne transportation functions as an instrument of sea power even when it operates from a land base, as was true of the British Coastal Command in World War II. It is also true that aircraft operating from carriers represent the extension of sea power even when they are attacking targets deep inland. Except for the great increase in bombardment of shore or inland targets from the sea, the functions of sea power were the same in World War II as they were in the 16th century, when warships specifically designed for fighting (as distinguished from armed merchantmen) first appeared.

Early Warships.—The coming of the first modern naval vessels designed and operated as warships coincided in time with the abandonment of oar propulsion and with the mounting of "great artillery" on ships. The broadside arrangement of guns was not compatible with the use of oars and the oars themselves were made unnecessary by developments in the art of sailing. The standard fighting ship in the English Navy became the galleon, a ship with two or three decks carrying its main batteries in the broadside and lighter pieces fore and aft. Armed merchant ships of 300 tons burden and over, called "great ships," supplemented the galleons. Such were the ships that won the great victory in 1588 over the Spanish Armada (*q.v.*), which contained large, slow ships with relatively few short-range guns. The Spanish ships were supposed to close with the enemy so that the soldiers with which they were crowded could board the enemy vessels. Thus the English victory was the victory of a new and revolutionary conception of naval battle: the English ships refused to let the Spanish ships get close enough for boarding and pounded them with guns of superior range and power.

It soon became evident that the ship that was powerful enough to be the mainstay of the fighting fleet and to meet on more or less equal terms the best ships the enemy could bring into battle was too large and too expensive—and also too heavy and too slow—to serve those functions of sea power that required numerous armed ships of good speed. For example, the pursuit and capture of enemy merchant vessels required the kind of ship that early became known as a cruiser. Thus during the 17th and 18th centuries the warship evolved into two major types. The main fighting ship of the fleet was the "ship of the line" or "line-of-battle ship," so called because it was meant to "fight in the line." Such ships were two-deckers or three-deckers (rarely also four-deckers) with heavy broadside armament as well as heavy timbers in their walls to keep out enemy shot. The other main type comprised the lighter and faster cruisers, of which the largest was the frigate, a vessel with a single deck of guns of lesser calibre than those of the line-of-battle ship. Like the frigate (but smaller) was the corvette, and below it came the sloop of war, usually employed as a dispatch vessel. The designations "frigate" and "corvette," after having been out of use for 100 years, were restored during and after World War II to denote warships that were intended mostly for escort work and were intermediate in size between cruisers and destroyers.

Modern combat ships fall into three major categories: (1) ships that fight chiefly by means of the aircraft launched from their decks; (2) those that fight primarily with guns or with rocket-propelled missiles; and (3) those that fight mainly with under-

water weapons such as mines, torpedoes, and depth charges. Among the latter is a further sharp distinction between surface and submarine craft. The fact that submarines also launch intermediate-range missiles indicates the extent of overlap among the three categories.

Aircraft Carrier.—The aircraft carrier (*q.v.*) appeared at the very close of World War I, the first being the British "Argus." Early in World War II carriers of the Royal Navy played an important part, as in the Mediterranean Battle of Cape Matapan (March 1941) and in the dramatic and successful chase of the German battleship "Bismarck" (May 1941) in the North Atlantic. In the Pacific campaigns the carrier won for itself the dominant place in the battle fleet, taking the position of primacy that the battleship had enjoyed for three centuries. The carrier was a floating air base that combined the mobility and sea-keeping power of the large warship with the advantages deriving from the use of aircraft. In the later stages of World War II, the U.S. Navy was able to concentrate such numbers of carriers in its task forces as to enable them to overwhelm with their aircraft the local air defenses of the archipelagoes against which they moved. Carriers furnished the major ground-support aviation to the United Nations during the early phases of the Korean War (1950-53) before air bases were established ashore, and they continued throughout the war to provide a valuable supplement to land-based aviation. Carrier-based planes also played a major role in Vietnam in the mid-1960s.

The addition of atomic weapons to its magazine enabled the carrier to bid for an important part not only in limited war on the Korean model but also in strategic bombing in any general war, though partisans of land-based (or submarine) bombardment power maintained that these same weapons had made the large carrier much too vulnerable to be worth its huge cost. The navy reply stressed the argument that the mobility of the carrier gave it a kind of protection not available to air or missile bases. With nuclear propulsion the mobility of the carrier was greatly increased.

The large carriers in the U.S. Navy are called attack aircraft carriers; others, designated support aircraft carriers, are considerably smaller, originally being built on converted cruiser hulls. During World War II a large number of escort carriers, nicknamed "jeep" carriers, were built on converted merchant ship hulls. They were invaluable for providing air support to the antisubmarine patrols in mid-ocean.

Battleship.—The battleship (*q.v.*), a direct descendant of the old line-of-battle ship, represented the gunpower of a fleet in its most impressive form. It was designed to stand up, along with its mates, to the most powerful gun-fighting ships in an enemy fleet. The largest of the Allied types in World War II reached a size of approximately 58,000 tons displacement, much of it devoted to armour; it carried 14-in. or 16-in. guns in U.S. and British types and up to huge 18.1-in. guns in two Japanese ships; it also carried an array of as many as 150 lesser guns for antiaircraft purposes; and in the case of the "Iowa" class it boasted a speed equal to or surpassing that of most cruisers. This prodigious piece of fighting machinery became obsolescent as its guns were far outranged by the bomb- and torpedo-carrying aircraft launched from carriers. Any hope that it might still serve a useful function disappeared in face of the development of missiles with nuclear warheads that could be mounted on a destroyer and could easily outrange and totally destroy any type of gun-firing ship. In the early 1960s neither the Royal Navy nor the U.S. Navy retained any battleships in commission, though the U.S. Navy had several in the reserve fleet.

Cruiser.—The cruiser (*q.v.*) is a gun-firing or rocket-firing ship, smaller than the battleship and designed to cost less to build and operate so that larger numbers can be made available for patrol purposes. In size and armament, cruisers have ranged from types that were almost indistinguishable from battleships to those very close to the size of a destroyer. The battle cruiser of World War I had the size and gun calibre of a battleship but sacrificed weight of armour for greater speed. The U.S. Navy used the term "large cruiser" for three vessels of the "Alaska" class built in World War II, displacing about 27,000 tons each and carrying 12-inch guns. Similar vessels in foreign navies, like the German "Gneisenau" and "Scharnhorst" and the French "Dunkerque" and "Strasbourg," were called battleships. Definitely in the cruiser category, however, are fighting ships that range from about 5,000 tons standard displacement to 17,000 tons (in the U.S. "Salem" class).

The well-known distinction between light and heavy cruisers does not refer to the size of the ship but to the size of its guns. The Washington Naval Limitation Treaty of 1922 specified that vessels carrying guns of from 6.1 in. to 8 in. (the limits then set for cruisers) should be termed heavy cruisers. Ships with smaller guns should be called light cruisers.

Destroyer.—In the category of vessels whose weapons are mainly of the underwater type are the destroyer and the submarine (*qq.v.*). The modern destroyer is a vessel of less than 3,500 tons displacement, carrying in the U.S. Navy guns of the same size (dual-purpose 5-in.) as some of the smaller light cruisers. However, it carries fewer such guns, usually five and only rarely as many as eight, and sacrifices armour entirely. Some of its guns have been replaced with guided missiles.

The destroyer takes its name from the fact that it was originally designed to destroy with its guns the torpedo boats that menaced the battle fleet (hence, "torpedo-boat destroyer"). Later the destroyer acquired both the torpedoes and the function of the boats it had been designed to destroy. In World War I the destroyer with its depth charges became the chief means of fighting submarines, and thus an essential escort vessel. For the latter purpose it was supplemented in World War II by the destroyer escort, a slower, smaller, and cheaper vessel, much more easily constructed and manned, built in large numbers to cope with the German U-boats.

Submarine.—The submarine had its prototype in a one-man vessel designed and built during the American Revolution by David Bushnell, and actually tried, though without success, against British warships. The submarine became an important naval vessel when on the eve of World War I it adopted the diesel engine, the periscope, and the gyrocompass. Its tactical advantage lay in its ability to gain concealment and protection by slipping under the waves. It was the only type of warship that could operate independently for extended periods in seas otherwise dominated by the enemy. Its torpedoes enabled it to attack vessels of all sizes, including battleships and aircraft carriers, but its greatest triumphs were achieved against merchant ships. The tremendous tonnages of Allied shipping sunk by the German U-boats in 1917 and again in 1942–43, and the comparable accomplishments of U.S. submarines in the Pacific during the whole of World War II, showed the potentialities of a submarine offensive against an opponent lacking the specific means of defense.

The versatility of the submarine was demonstrated in World War I when submarines not only fired torpedoes and laid mines but came to the surface on occasion and used their deck guns against unarmed merchantmen. The experimental British M-class of three vessels actually mounted 12-in. guns. The large French submarine "Surcouf" used in the early part of World War II carried on its deck two 8-in. guns and a hangar for a seaplane. Submarines also proved useful for patrolling and for special assignments such as landing a few men on a coast to carry out a secret mission. This versatility was vastly increased with the development in the United States of the nuclear-powered submarine capable of discharging while submerged ballistic missiles with nuclear warheads and with a range of over 1,500 mi.

The overwhelming defeat ultimately suffered by the German U-boats in both world wars was due to the characteristic weaknesses of undersea craft of the time, especially their low submerged speed. But developments after World War II promised to wipe out some of these disadvantages. The introduction of nuclear propulsion gave the submarine almost unlimited range and enabled it to travel at high speeds while submerged. Because it does not waste power in producing wave action, a submarine can have a greater speed submerged than afloat for any given propulsion thrust. The submarine also increased the depth to which it could dive, modern maximum depths being secret but certainly more than

800 ft. In addition, the use of missiles with nuclear warheads gave it a strategic bombardment capability.

Other Types.—Intermediate between combatant and noncombatant types are the vessels that lay and sweep up mines. Ships of almost all sizes and types have served as minelayers, including submarines and cruisers, and their strategic importance in both world wars was enormous. A small and slow but indispensable and especially valiant ship has been the minesweeper. The development of new techniques for dealing with ever more ingenious types of mines has been one of the great sagas of modern naval warfare (*see* MINE, NAVAL).

Ships that are not used directly in combat but enable combat vessels to function are tenders of various kinds, repair ships, store ships, oilers, fleet tugs, transports, cargo ships, hospital ships, and various other vessels that go to make up what is known as the "fleet train." In the latter stages of World War II in the Pacific, the technique of using a fleet train was perfected to the point of enabling battle squadrons or "task forces" to achieve a range and sea-keeping capability unknown at least since the days of sail.

Bases.—Comparable to the fleet train but immobile and more elaborate in its facilities is the naval base or naval air station. The importance of bases to sea power has been reflected in centuries of struggle to acquire and retain them. Britain's ability after the Dutch Wars of the 17th century to contain the whole continent of Europe with sea power stemmed not alone from its continuing though sometimes tenuous superiority in ships and seamanship but also from the possession of a particularly advantageous system of bases, most of which had been acquired through the exercise of sea power. The first and greatest British naval base was the United Kingdom itself, with its many fine harbours, splendidly situated for the control of sea-lanes from northern and western Europe to other countries. Bases at Gibraltar, Malta, and Alexandria in the Mediterranean enabled the British to control the southern exits from Europe.

The entire Pacific campaign of World War II was mostly a contest for bases that would enable American naval and air power to exercise their dominance closer and closer to the heart of Japan. The great fleet train could supplement the bases but could not substitute for them. It was the acquisition of the Mariana Islands, Iwo Jima, and Okinawa that finally enabled Allied air and naval power to hurl the blows that brought Japan to her knees. On the other hand, mobile fighting power could acquire through capture the bases necessary to its function, but no number of land bases could substitute for a gross shortage of floating fighting power.

The Role of Sea Power.—The usually great and sometimes decisive importance of sea power in war has been generally appreciated in modern times by maritime nations. But the incisive summing up of the role of sea power was the work of Alfred Thayer Mahan, a captain (later retired as a rear admiral) in the U.S. Navy. In 1890, toward the end of his active service career, he published *The Influence of Sea Power upon History, 1660–1783,* which described and analyzed the part of sea power in the great struggles of the period indicated in the title. This book gained extraordinary attention and won for its author not only enduring international fame but also the assurance of a large audience for each of the many succeeding volumes on naval history and strategy that he published. The German kaiser was one of the several national leaders who were captivated by Mahan's books, which stirred up at least equal interest also in Great Britain. Thus Mahan's labours provided ideological impetus to the great Anglo-German naval race that preceded World War I.

One who reads Mahan's sober and scholarly volumes today may find it difficult to understand the excitement they caused and the undoubtedly great influence they had on the naval policies of the major powers of his time, including the United States and Japan. Even after his death, Mahan's views continued for a considerable time to enjoy respect if not veneration. His emphasis on the role of sea power in war, which could not fail to result in some exaggeration, was intensified by others who found his message attractive. Where Mahan himself had used the cautious word "influence," others spoke of sea power as if it inevitably determined the course of every major war. World War I was later interpreted by many writers as having been essentially decided by the naval blockade of Germany, some going so far as to assert that the gigantic struggles ashore were just so much useless bloodletting.

Actually, the Allied blockade would not have been so important militarily if the battles ashore had not used up resources which the blockade prevented the Germans, but not the Allies, from replenishing. Also, had the initial German war plan (the Schlieffen Plan) succeeded, as it almost did, the war might have been decided ashore very quickly—as the Franco-German War had for all practical purposes been decided in a few weeks in 1870 despite clear French naval superiority. It was the stalemating of the battle lines in Europe following the first Battle of the Marne that permitted Allied sea power to exercise its throttling effect. In any case, the Allied naval contribution to victory was actually much greater than is symbolized by the word "blockade," since British and later American participation in the war hinged upon the successful use of sea power to transfer men and commodities overseas. Thus, one of the truly decisive campaigns of the war was the battle in the Atlantic against the German U-boat—a battle that was to take place again during World War II.

Following World War II, on the other hand, popular opinion—and also much professional opinion—regarding the experience of that war was distorted in the opposite direction. Germany's lesser vulnerability to the effects of blockade as compared with her situation in the previous war, and the new and dramatic role played by tactical and strategic air forces caused many observers to withhold due credit from Allied sea power despite its enormous and vital contribution to victory. World War II was in fact the conflict in which sea power reached the apogee of its influence on history. The first great air war and the war that saw the most titanic battles of all time on land was also by far the greatest of naval wars. It could hardly have been otherwise in a war that was truly global, where the pooling of resources of the great allies depended upon their ability to travel the highways of the seas. The sometimes threatened but always maintained maritime communications, especially between the United Kingdom and the United States, and also between them and the Soviet Union, provided a sharp and telling contrast with the isolation from each other suffered by three major Axis powers. Even Germany and Italy, though contiguous, were prevented by Allied sea power from using those sea communications that in peacetime had carried the bulk of their commerce with each other.

Similarly, the critical role played by United Nations and especially U.S. sea power in the Korean War lacked dramatization because of the absence of naval opposition—except from mines laid defensively in large numbers around the ports of North Korea, especially Wŏnsan. But overwhelming UN naval superiority was the key factor that made it possible to resist Communist aggression in Korea. Aircraft carriers also provided important aviation support to UN ground forces, especially in the critical early phases of the war.

Naval forces also made possible several amphibious operations, including the spectacular "envelopment from the sea" at Inch'on, where U.S. forces were landed on the flank of and behind Communist lines, causing a complete collapse of the enemy position and a precipitate retreat (*see* KOREAN WAR).

Nuclear Weapons and the Future of Sea Power.—The development of nuclear weapons necessitated an entire reevaluation of the role of sea power. Even if it is assumed that a nation under bombardment by numerous thermonuclear weapons could continue to maintain a navy, which might itself be a target for such weapons, a general war of that kind would almost certainly move too fast to permit sea power to exercise its traditional function. But against this proposition two important facts have to be assessed. First, with the new kinds of forces being made available to it, especially in the form of missile-launching submarines and other missile-launching vessels, the navy of the future may play an important and possibly a dominant role even in general war, though strictly of a bombardment nature. In other words, the function that was once decidedly subsidiary to other functions involving control of sea communications could become the only important one in general war. Second, if the war of the future is a limited

war on the Korean model, it will call upon naval power to play much the same part it has played in many wars of the past.

SEA SERPENT. Enormous serpents, both terrestrial and marine, are subjects around which have arisen such an array of legends and stories that it is almost impossible to disentangle fiction from fact. So far as terrestrial snakes are concerned it seems fairly safe to assume that there are none in the few remaining unexplored parts of the world that greatly exceed in size those that are already known. In the depths of the sea, possibly, may still be gigantic creatures of which there is no knowledge. Such a creature, however little related to the true serpents, would still qualify very well for the popular idea "sea serpent."

Up to the present no animal has been captured that has not, on examination by competent persons, proved to belong to a previously well-known group. A large number of the well-authenticated stories of monstrous marine creatures seem to be explicable as incorrect observations (because of abnormal visual conditions or ignorance) of animals already quite well known.

Many possible explanations have been put forward to account for sea serpents. A number of porpoises swimming one behind the other and rising regularly to take air might produce the appearance of a very large serpentlike creature progressing by a series of vertical undulations. A flight of seafowl and a brood of ducks have been mistaken for a large snake swimming at the surface of the water. Large masses of seaweed half awash have, on more than one occasion, been believed to be some gigantic animal. Basking sharks (*Cetorhinus maximus*), which have a habit of swimming in pairs one behind the other with the dorsal fin and the upper lobe of the tail just above the surface, produce the effect of a body 60 ft. or more long; even a simple partially decomposed specimen which was cast ashore was reported in all good faith as a sea serpent.

In the same category as basking sharks may be mentioned tunnies (*Thunnus thynnus*), porbeagles (*Lamna cornubica*) and chimaeras (*Chimaera monstrosa*), which at various times have been incorrectly recorded by observers unfamiliar with them. Ribbonfishes or oarfishes (*Regalecus*), which attain a length of 20–30 ft. and are snakelike in shape, have been suggested as the possible explanation of some so-called sea serpents, particularly of those reported from the Mediterranean, where these animals are most common. Nemertines, which may reach a length of 30–45 ft., have also been suggested as a possible explanation of some records. Sea lions when breaking surface for breath might, if seen from an unfamiliar viewpoint or in a fading light, be mistaken for much larger, snakelike animals.

Giant squids (*Architeuthis* species) are undoubtedly the foundation on which many accounts are based; these animals, which may attain a total length of 50 ft., are sufficiently uncommon to be unfamiliar to the majority of persons. They do occasionally frequent those regions from which many accounts of sea serpents have come—Scandinavia, Denmark, the British Isles and the eastern coasts of North America. One of these animals swimming at the surface with the two enormously elongate arms trailing along through the water would produce almost exactly the picture that many of the strangely consistent independent accounts require; a general cylindrical shape with a flattened head (=posterior end of the squid's body), appendages on the head and neck (=lateral fins and edge of mantle), colour dark, lighter beneath, progression steady and uniform, body straight but capable of being bent and spouting water (=water ejected from siphon). Further, sperm whales are known to kill and devour *Architeuthis* and similar cephalopods, and one of the most graphic accounts of the sea serpents speaks of it as in conflict with a whale around which it had thrown two coils and which it ultimately dragged below the surface; actually, it seems quite probable that the whale was eating a giant squid whose tentacles, thrown round the whale in the struggle, were mistaken for the coils of a snake, and that the whale, far from being dragged under, merely sounded with its prey in its mouth. A. C. Oudemans in his *The Great Sea Serpent: an Historical and Critical Treatise* (1893) gives a full account of all these possibilities.

A stranded animal carcass on the coast of Lower California was plausibly reported as a sea serpent. The remains were those of a large beaked whale. The body had been eviscerated (by sharks presumably) and the skin remaining was twisted up so that between the huge head and the large body there appeared to be a long and plesiosaurlike neck.

The discovery of an enormous eel larva in the Pacific, for which no adult is known, suggests that there may be an undiscovered gigantic kind of eel. This would of course perfectly satisfy the popular concept of a sea serpent. (H. W. P.; K. P. S.)

SEASICKNESS: *see* MOTION SICKNESS.

SEASONS, divisions of the year according to consistent changes in character of weather in the course of the annual cycle. The seasons named in European languages are associated with a yearly cycle in the life of plants, particularly of cultivated plants. Winter is the season of dormancy, spring that of sowing (Lat. *satio[n]*, whence Fr. *saison*, Eng. season) and germination; summer is the period of growth and maturity and autumn the time of harvest. This fourfold division of the year can seldom be recognized in the annual cycle of weather itself.

Outside the tropics, the essential characteristic of this cycle is

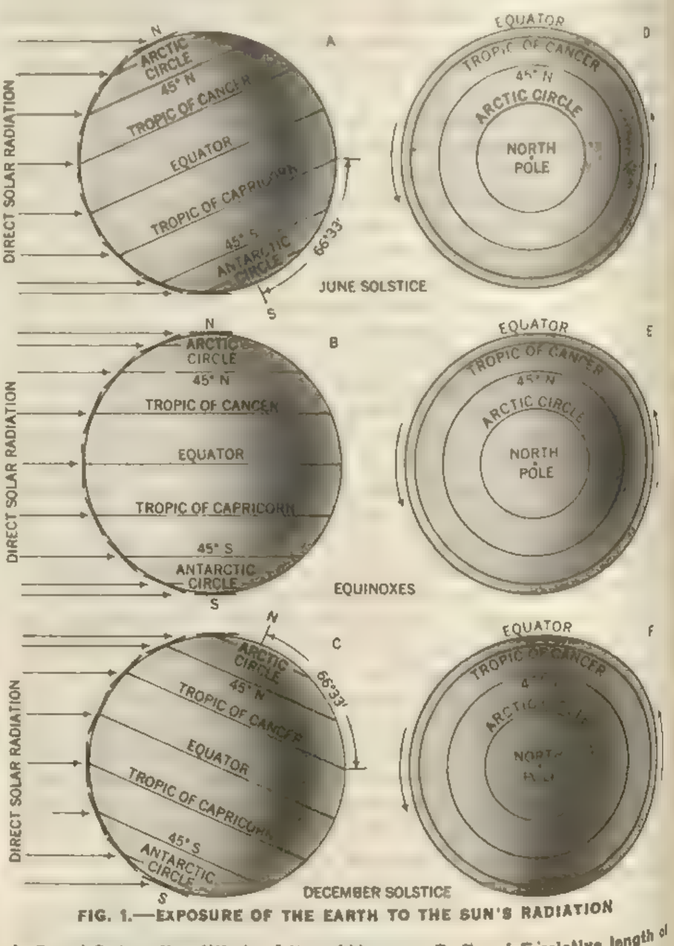

FIG. 1.—EXPOSURE OF THE EARTH TO THE SUN'S RADIATION

A, B and C show the attitude of the midday sun; D, E and F relative length of daily periods of sunshine and darkness

a pendulation of temperature between a single maximum and a single minimum. Other differences among the seasons are subordinate to the cycle of temperature. Thus, only the extreme seasons have a distinctive character; if the husbandman's yearly round had not left so profound an impress on European speech, spring and autumn would be considered merely transitional periods, hardly worthy of names co-ordinate in rank with those of summer and winter.

In the tabulation and discussion of climatologic observations made in middle and high latitudes, it is customary to combine the calendar months into seasons as follows:

Northern hemisphere:	*Winter*	*Spring*	*Summer*	*Autumn*
	December	March	June	September
	January	April	July	October
	February	May	August	November
Southern hemisphere:	*Summer*	*Autumn*	*Winter*	*Spring*

This division is only a convenience; in the appropriate northern latitudes March and November may be in fact winter months, May and September summer months. In relation to crops, the year is often divided into two parts, separated by the dates of the earliest and latest killing frosts in autumn and spring respectively.

Solar Radiation.—The seasonal changes of temperature are dependent upon the annual variation in the angle of the sun's rays and in the length of daylight, which determine the amount of solar radiation absorbed daily by the surface of the earth and the atmosphere (*see* CLIMATE AND CLIMATOLOGY: *Climatic Controls; Solar Radiation*). Assuming a cloudless sky and constant transparency of the atmosphere, the amount of solar radiation received at a point on the earth's surface at any moment is approximately proportional to the sine of the angular height of the sun above the horizon (the solar altitude). The amount received during any day evidently increases with (1) the length of the daily period of sunshine and (2) the sun's altitude at the successive moments of the day. The contrast between summer and winter is the result of seasonal variation in these two factors. Both have their maximum at the summer solstice and their minimum at the winter solstice. They result, in turn, from the changes in exposure of the earth to the solar radiation during its annual revolution about the sun. As the earth moves in its orbit, its axis maintains a nearly constant orientation in space, inclined about 66°33′ to the plane of the orbit. Figure 1, A, B and C, show the attitude (position) of the earth's surface with respect to the sun's rays at the solstices and equinoxes. The lines tangent to the meridian at the left of the diagrams represent the plane of the horizon at selected latitudes. The smaller of the two angles made by one of these lines and the shaft of the arrow that represents the solar rays is the sun's altitude at noon on the day and in the latitude indicated.

Diagrams D, E and F of fig. 1 illustrate the seasonal variation in length of the daily period of sunshine in the northern hemisphere. The great circle that separates the illuminated and shadowed hemispheres swings in an annual period back and forth across the segments of the earth's surface enclosed by the polar circles. In the daily rotation of the earth, any point in the hemisphere (except a segment near the pole at times other than the equinoxes) is carried alternately through sunshine and shadow. The part of the daily cycle during which the sun is above the horizon at any point is represented by the fraction of its parallel of latitude that lies within the illuminated hemisphere, and the part during which the sun is below the horizon by the fraction of its parallel that lies within the shadowed hemisphere.

The graphs of fig. 2 show the annual variation, by weeks, of the average daily amount of radiation from sun and sky actually received on a unit horizontal surface (the average "insolation") at four stations in North America. Outside the tropics, the maximum and minimum of the annual march of insolation usually fall near the solstices. The amount of heat produced by insolation depends on the fraction that is absorbed. Among types of surface common on the earth, a snow cover reflects most and absorbs least of the incident radiation. Hence, the annual march of absorbed radiation on land surfaces that are covered with snow

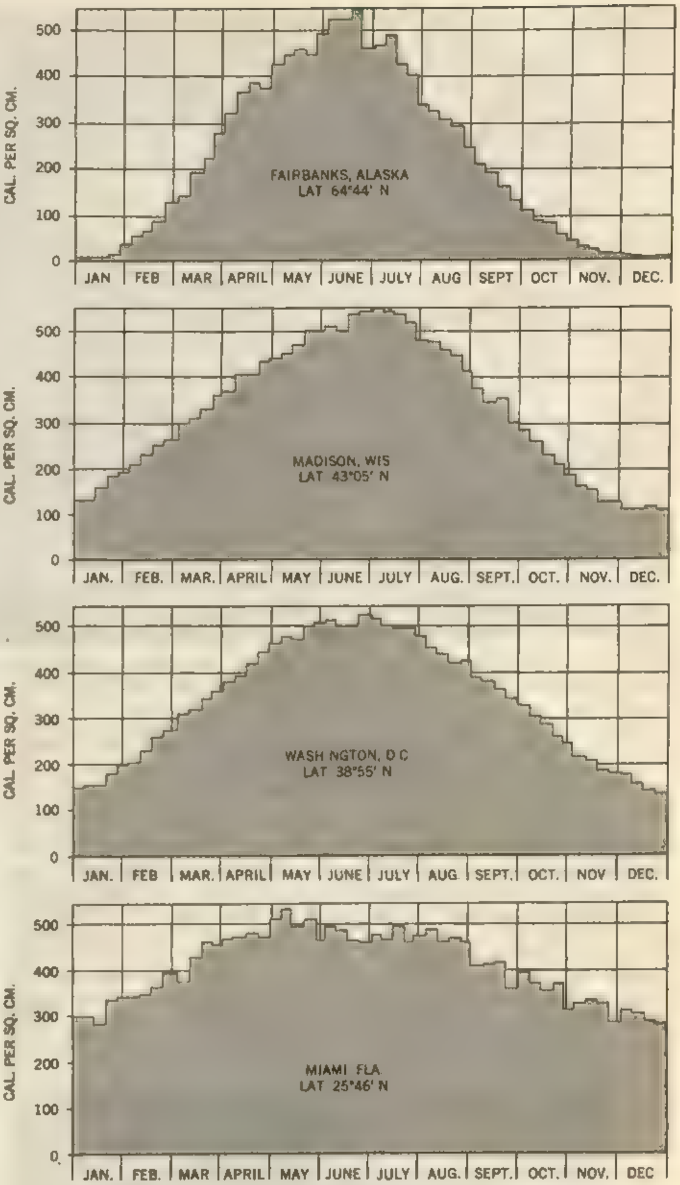

FIG. 2.—RADIATION FROM SUN AND SKY

Weekly means of daily amounts of radiation received on unit horizontal surface at four stations in the United States. Data from U.S. Weather Bureau

in winter and free of snow in summer has a larger amplitude than is suggested by the total incident radiation plotted in fig. 2, since a larger fraction of the total is absorbed in summer than in winter.

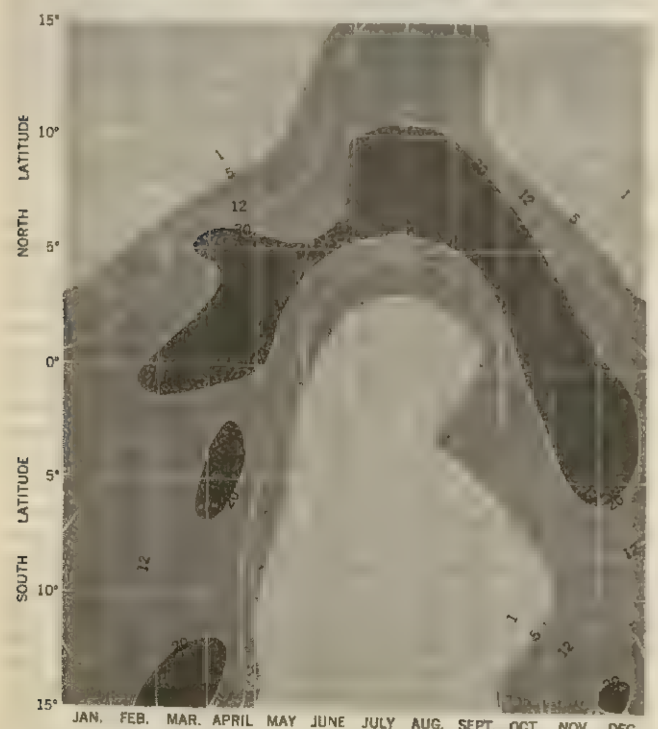
Annual Temperature March in High and Middle Latitudes.—The temperature of the air near the earth's surface, whether land or water, follows closely the temperature of the surface itself. How large a rise in temperature of the surface and the air close to it is produced by the absorption of a given amount of radiation depends on the disposition of the heat so produced. If heat is removed rapidly from the surface as radiation is absorbed, whether into the air, by radiation into space, or downward into the substratum, the temperature at and near the surface rises less than it does if the heat is removed more slowly. The processes that remove heat most rapidly from an absorbing surface are evaporation of water, the blowing of cool air over the surface and, in water bodies, the mixing, effected by the wind, of water at the surface with deeper water. All these processes reduce the rate of warming, and prevent the temperature of the surface from rising to as high a maximum as is attained by dry surfaces not effectively cooled by wind.

A surface of land or water attains its maximum temperature at the time when it becomes warm enough to lose heat to the atmosphere and space as rapidly as it is gaining heat by absorption

of radiation. This equilibrium cannot be reached until after the maximum of the march of absorbed radiation; that is, in most places, after the summer solstice. It is attained when the curve that represents the rate of absorption of radiation, declining from its maximum, intersects the curve of loss of heat from the surface. The cooler the surface is, in relation to the radiation absorbed, the longer is the time required for the curve of absorbed radiation to decline to the level of the curve of loss of heat. With a given march of absorbed radiation, therefore, the maximum of the annual march of temperature occurs later at cooler surfaces than at warmer ones.

A corresponding effect on the minimum of the march of temperature is produced by the return to the surface in winter of the heat transferred downward into the substratum in the preceding summer. With a given annual march of absorbed radiation, the amount of heat accumulated in the oceans and large lakes in summer and returned to their surfaces in winter is many times the turnover of heat below a land surface. Again with a given annual march of absorbed radiation, the larger the turnover of heat the higher is the temperature of the surface at its annual minimum, and the longer is the minimum delayed after the winter solstice. Thus, the characteristic differences in annual march of air temperature between the oceans and the lands that are embodied in the terms "maritime" and "continental" arise from the difference in annual heat turnover below their respective surfaces. Over the land, the maximum and minimum of the annual march of air temperature occur about one month after the solstices. Over the oceans, they are retarded about two months. As a result of the circulation of the atmosphere, the margins of the continents share the maritime regime of temperature.

Seasons in Low Latitudes.—From middle latitudes toward the equator, the amplitude of the annual march of insolation diminishes, and the annual cycles of insolation and temperature become increasingly susceptible to distortion by seasonal variation in cloudiness and rain. In fig. 2, there is a suggestion of flattening at the peak of the march of insolation at Washington, D.C., the consequence of summer cloudiness; and at Miami, Fla., the peak is broadly flattened. In tropical latitudes, seasonal differences in weather depend more on the shifting of the great wind belts of the earth than on the annual march of insolation. The alternation of rain and drought becomes more important than the



ADAPTED FROM KOPPEN, "DIE KLIMATE DER ERDE: GRUNDRISS DER KLIMAKUNDE"

FIG. 3.—MEAN MONTHLY PRECIPITATION, IN CENTIMETRES, ALONG THE MERIDIAN OF 15° E. LONGITUDE WITHIN 15° OF THE EQUATOR

change in temperature through the year. Seasonal alternation of rain and drought itself produces seasonal change in temperature, rainy seasons in the tropics being almost without exception cooler than dry seasons, regardless of the time of year in which the seasons occur.

The zone of convergence between the trade winds of the two hemispheres is a rainy belt, and rainy weather accompanies it as it swings northward and southward in its annual cycle. Where the belt is narrow, its pendulation may bring two rainy and two dry (or less rainy) seasons per year to places near the equator. Fig. 3 shows the distribution of precipitation through the year in the western part of equatorial Africa, along the meridian of 15° E longitude. There the meteorologic processes are more nearly symmetrical with respect to the equator than in any other land area in comparable latitudes. Between the equator and the parallel of 5° N latitude a fairly symmetrical sequence of two rainy and two dry seasons in the course of the year may be identified. In most tropical areas, however, the alternation of seasons includes no more than one rainy and one dry season. Relief of the land and exposure to winds from different directions introduce exceedingly wide variations in length and intensity of these seasons.

In India a strongly marked seasonal alternation of rainfall and drought extends northward into latitudes in which there are distinct temperature seasons, summer being rainy, winter dry. The result of this superposition of seasons based on temperature and on raininess is a sequence of three seasons of different lengths: a cool season in the months December–February, a hot season from March to mid-June and a rainy season from mid-June to November. The warmest season thus precedes the rainy period, in which cloudiness strongly reduces insolation. A similar superposition of temperature and rainfall seasons is observed, though in less extreme form, in the outer parts of the tropical belt in Africa and South America. In those continents the highest temperatures of the year are sometimes recorded before the rainy season, sometimes after it.

SEATON VALLEY, an urban district (1935) in the Blyth parliamentary division of Northumberland, Eng., 8 mi. NNE of Newcastle. Pop. (1961) 26,095. Area 19.5 sq.mi. The district lies in the centre of the south Northumberland coalfield and has ten mines employing the greater part of the population. Other industries produce heat-resisting materials, bricks, fire-lighters, and briquettes; agriculture ranks second to coal in importance.

Seaton Valley comprises ten mining villages; the biggest are Cramlington, Shiremoor, and Seaton Delaval. The latter, the administrative centre, takes its name from the De la Val (Delaval) family, which dates to Norman times. Seaton Delaval Hall (1720), just outside the district, is one of Sir John Vanbrugh's great achievements; nearby are the mausoleum (1776) and Sterling Castle (a ruin), both built by Delavals. Backworth Hall (1780) is a miners' welfare centre.

SEATTLE, the chief city of Washington, U.S., situated on a neck of land between Elliott bay (Puget sound) and Lake Washington (freshwater); a port of entry, headquarters of the Washington customs district; the seat of King county and the largest city of the Pacific northwest. It is 125 nautical miles (232 km.) from the Pacific ocean; 110 mi. S. of the Canadian border. Seattle's population was 557,087 in 1960. The standard metropolitan statistical area includes King county and, from 1959, Snohomish county; the population in 1960 was 1,107,213. The 1960 census showed nine other cities in the metropolitan area with a population over 5,000: Renton, Auburn, Kirkland, Kent and Bellevue in King county, and Everett, Edmonds, Lynnwood and Marysville in Snohomish county. (For comparative population figures *see* table in WASHINGTON: *Population*.)

Central Seattle is situated on a series of hills, some reaching 500 ft. above the harbour, in surroundings of great natural beauty.

WIDE WORLD

THE SEATTLE WORLD'S FAIRGROUNDS WITH MT. RAINIER IN THE BACKGROUND. AT RIGHT THE 600-FT. SPACE NEEDLE

Ninety miles to the south in the Cascade range is Mt. Rainier (*see* MOUNT RAINIER NATIONAL PARK). To the west, beyond Puget sound, rise the jagged Olympic mountains, which shelter the city from the heavy winter rains and winds of the coast. Beyond Lake Washington to the east are the high Cascades, which protect Seattle from the winter cold of the mid-continent. Prevailing winds (average velocity 8.9 m.p.h.) are from the southwest in winter and the northwest in summer. Average annual precipitation is 33.44 in. (84.9 cm.), two-thirds of it falling between October and March.

The salt-water harbour measures five miles across from West point on the north to Alki point on the south, and includes the east, west and Duwamish waterways, extending inland on the south side of the bay; Smith cove, on the north side; and Shilshole bay, the western outlet of the Lake Washington ship canal, north of West point. The canal (8 mi. long, minimum depth 28.5 ft.) connects Puget sound with Lake Washington, passing through Lake Union. The locks near the west end of the canal, which overcome the difference of 26 ft. between water levels, accommodate ships 760 ft. long. Elliott bay, where shipping is concentrated, has an entrance width of 2.5 mi. and is very deep and free from natural obstructions. Along the water front the hills have been graded down to give a comparatively level area for the business district. This is built up with several large hotels, public buildings (including the modern public library, 1960), and high business buildings, most of them erected either after World War I or in the post-Korean war building boom. A concrete pontoon bridge across Lake Washington, the floating portion of which is 6,561 ft. long, was completed in 1940. A second Lake Washington bridge, northwest of the first, was completed in 1963.

History.—The first white settlement was made at Alki point in Nov. 1851 by a group of middle westerners, most of whom moved around on Elliott bay the following February. The new town was named for a friendly Indian chief. In 1853 a plat was filed and Seattle became the seat of King county, Oregon territory. Later that year the region became part of the newly proclaimed Washington territory. Lumbering was the chief activity, the steam sawmill of Henry Yesler giving Seattle its early importance. By 1855 the population was 300. In Jan. 1856 it was attacked by neighbouring Indians and successfully defended by the U.S. sloop of war "Decatur." The city was incorporated in 1869. Early growth was slow, the 1870 census showing a population of 1,107, which rose to only 3,533 in 1880; in this period the chief exports were lumber, fish and coal (from the mines to the east and south of Lake Washington). After 1880 the rate of growth increased rapidly. In 1883 a spur line connected the city with Tacoma, main terminus of the Northern Pacific, the first transcontinental railroad to reach Puget sound. For some years thereafter (a period of intense rivalry between Seattle and Tacoma) this rail service was unsatisfactory. Not until 1893, when the Great Northern reached the city, did Seattle become a full-fledged rail terminus. In 1889, the year Washington attained statehood, most of the business district of Seattle burned but this did not hamper the city's growth. The population in 1890 was 42,837. The arrival of the first Japanese steamer in 1896 marked the beginning of considerable foreign trade.

Of greater significance was the Yukon mining strike, which touched off the great gold rush beginning in 1897. Almost overnight Seattle became an important commercial centre, the outfitting point for prospectors and the port to which they shipped their gold.

Subsequent Alaskan gold strikes, notably at Nome and Fairbanks, gave more impetus to Seattle's growth. Led by City Engineer Reginald H. Thomson, Seattle prepared for the future by grading the downtown hills (a project lasting for decades), by securing an abundant supply of water from Cedar river (in the Cascades, 26 mi. S.E.) and by building the first municipally owned hydroelectric plant in the country (1905). In 1909–10 the Alaska-Yukon-Pacific exposition was held at Seattle. Between 1905 and 1910 ten cities and towns were annexed and the city's population grew to 237,194. By 1910 Seattle had been reached by two other major railroads. The opening of the Panama canal in 1914 gave a new stimulus to the city's commerce, as did the completion of the Lake Washington ship canal two years later. During World War I Seattle built more ships than any other port of the U.S. The average number of wage earners in the city's manufacturing establishments rose in five years (1914–19) from 11,523 to 40,843; the value of the output, from $64,475,000 to $274,431,000. During the same period unions grew rapidly but the labour movement suffered a major setback with the failure of a general strike in 1919 that lasted for five days. The 1920 census showed a population of 315,312. The decade of the 1920s was one of moderate growth; that of the 1930s was one of stagnation and depression. World War II brought a great boom, with shipyards and the aircraft industry playing important roles.

The period after World War II was characterized by a resumption of the rapid growth of population, with an increasing diversity of industry.

Between April and Oct. 1962 the "Century 21" exposition (Seattle World's fair) was held on a 74-ac. tract of land one mile from the central shopping district with which it was connected by a high-speed monorail train. In addition to its own cultural and commercial values, the exposition left a legacy in the form of renovated and new permanent civic buildings.

Government.—The city is governed under a charter amended in 1946 to provide for a park superintendent and an administrative assistant to the mayor. Municipal elections are nonpartisan. The mayor and city councilmen are elected at large for four-year terms; beginning in 1962, council candidates had to file for designated positions on the ballot. The city owns its street transit, water supply and hydroelectric generating and distributing systems.

Harbour development and administration of public terminal facilities are in the hands of a public corporation called the Port of Seattle, created in 1911 by the people of Seattle and King county and administered by a three-man board of elected commissioners. Also under its jurisdiction is the Seattle-Tacoma International airport.

"Metro."—The Municipality of Metropolitan Seattle ("Metro") was established by popular vote in 1958, after the passage of an enabling act by the state legislature. Of the six functions authorized by the legislature (water supply, planning, rapid transit, parks-recreation, garbage disposal and sewage disposal), only the most pressing task of sewage disposal was permitted in the implementing act.

The Metro area, as initially established, covered 230 sq.mi. in northern King county, including ten incorporated cities and towns (Seattle, Renton, Bellevue, Medina, Clyde Hill, Hunt's Point, Beaux Art, Houghton, Kirkland and Bothell) plus unincorporated areas. Governed by a council consisting of representatives of the governmental bodies concerned, Metro quickly embarked upon the building of a sewage disposal system.

Commerce, Industry and Transportation.—Seattle is the leading commercial, industrial and financial centre of the Pacific northwest. Its geographical position in relation to the orient and Alaska makes it a natural receiving and distributing point for trans-Pacific and Alaskan traffic and the Panama canal gives access to Atlantic and Gulf markets, while the products of its tributary territory and its own manufactures supply staple articles for outgoing freight. A large part of the mail moving across the Pacific is handled in Seattle. In the early 1960s leading imports were limestone, lumber, gypsum rock, bananas and newsprint; the chief exports were coal, wheat, barley, tallow and wheat flour. Seattle is the principal outfitting point for the fisheries of the North Pacific and the chief supply point and wholesale market for logging camps and the agricultural northwest. Cheap electric power combined with abundant raw materials of certain kinds and distance from the older industrial centres has stimulated industry. The city has over 1,000 manufacturing establishments.

In addition to highway and railroad transportation facilities, Seattle is served by airlines with flights to Canada, Alaska, Japan and other points in the far east as well as to other points in the U.S. It is a port of call for steamers with sailings to Alaska and California, across the Pacific and through the Panama canal to eastern U.S. and European ports. It is the centre of the system of ferries owned by the state.

Education and Cultural Activities.—The public-school system includes elementary, special, junior high and high schools and a technical school. There are also Roman Catholic parochial schools and other denominational and nondenominational private schools. The University of Washington (*see* WASHINGTON: *Education*) is in Seattle. Other institutions of higher learning in the city are Seattle university (Roman Catholic, established 1891) and Seattle Pacific college (Free Methodist, chartered 1891). An educational television station broadcasts from the University of Washington. The public library system includes, in addition to the main library, several branches and bookmobiles, a municipal reference library and a library for the blind. Other cultural features of the city include the Seattle Art museum, the Frye Art museum, the Museum of History and Industry and the Seattle Symphony orchestra.

Parks and Recreation.—Seattle's public park system of over 3,500 ac. includes parks, community playfields, neighbourhood playgrounds, golf courses and beaches. The area also offers many opportunities for water sports and hunting and fishing.

SEA URCHIN, popular name for spiny marine animals, members of the Echinoidea, a class of the Echinodermata (*q.v.*). The name *Echinus*, applied to a common genus, refers to the similarity between some of the Mediterranean urchins and the European hedgehog, called *echinos* by the ancient Greeks, which when rolled up forms a spiny ball of similar size. The majority of the sea urchins, the Regularia, conform to this type, whereas the remaining, the Irregularia, cake urchins, sand dollars (*q.v.*), and heart urchins, deviate in many respects.

The regular sea urchins have a more or less spherical shell, or test, of closely fitting calcareous plates, arranged in five double rows, the radials, perforated by doubled pores, each pair admitting one tube foot, and five double rows without such pores, called the interradials. On the under side of the test is a large hole covered by skin; the mouth and the elaborate dental apparatus are placed in the centre of the hole. On the opposite pole is a smaller opening, the vent or anus. (*See* fig. 1.) The plates of the test carry smooth knobs, each articulating with a calcareous spine that can be moved by the action of basally placed muscles. The

size, form, and number of the spines determine the external appearance. In one primitive form, *Cidaris*, the larger primary spines, few in number and shaped like a policeman's night stick, are surrounded by a circle of smaller secondary spines. In *Diadema*, well known from most coral reefs, the spines are very long and slender and are effective as protective lances. (*See* fig. 2.) The long, thick spines of the slate pencil urchins (*Heterocentrotus*) were actually used as writing pencils by the early missionaries in the South Sea islands. A close relative has spines shaped like short flat discs, which fit together to form a mosaic of hexagonal plates. From muddy bottom in deep water is known one sea urchin with long slender spines, gently arched and with the tip expanded into a small hoof; by means of these modified spines the sea urchin can move over the soft bottom with little difficulty. A characteristic of most sea urchins is the pedicellariae—minute, three-pronged pincers, often provided with poison glands, borne

on slender stalks. They remove dirt, pass food particles along, and serve as effective weapons. From the five radial canals of the water vascular system, which characterizes all echinoderms, arise the podia or tube feet, which pass out through the pore pairs of the test and end in a terminal sucking disc.

The sea urchin's masticatory apparatus ("the Lantern of Aristotle") is a complex structure consisting of five ribbon-shaped teeth—rootless, like the incisors of a rodent—each of which is encased in a jaw, a triangular pyramid. Each jaw has the apex directed downward and is united by short muscles to its neighbours. From raised points along the edge of the large opening in the test extend five pairs of bandlike muscles, which attach to the lower part of the jaws. Five similar pairs of muscles, placed between them, attach to the upper ends, or bases, of the pyramids. By contracting or extending these muscles, the sea urchin can adjust its dental apparatus to facilitate chopping up larger pieces of algae, scraping off the minute algal growth on the rocks, grinding up smaller animals, and, in certain species, boring a hole in rock wherein the animal may spend its life. The majority of the regular sea urchins are vegetarians, but some live chiefly on smaller bottom animals and others subsist on the decaying debris of the muddy ocean floor.

Sea urchins are free-living forms, creeping on the sea bottom. They are able to move in all horizontal directions, at right angles to the axis that runs from the mouth to the anus. The Irregularia, however, are burrowers that have acquired a secondary bilaterality and can move in one direction only. In these forms, the anus has shifted down in one of the interradii and the radius opposite becomes the fore end.

In sea cookies, or cake urchins, and in sand dollars, which live in shallow water exposed to wave action, the test is thick, flattened and reinforced by internal pillars. The masticatory apparatus is preserved but modified. The mouth opening in the test is small and food is swept in along ciliated grooves and then sifted and ground up by the teeth.

In heart urchins, which live at greater depth on or in mud, the test is fragile and the mouth has moved forward and become a transverse slit; the complex dental apparatus has disappeared. Many of these forms live in burrows lined with mucus secreted by glands on the spines. The food is collected by means of long tube feet that reach up to the surface of the mud through a hole in the burrow and sweep up what organic particles there may be on the muddy surface.

There are about 700 species of sea urchins now in the seas, a fraction of what existed in former times. Because of their easily preserved skeletons, these forms constitute one of the most important groups of fossils used by students of paleontology. *See* also references under "Sea Urchin" in the Index.

SEBASTIAN, SAINT, a martyr believed to have suffered in Rome during the persecution of the emperor Diocletian. His feast day on Jan. 20 occurs in the early Roman martyrology of the chronographer of A.D. 354, as well as in 5th-century Hieronymian martyrology. According to his legend he was a captain of a Roman cohort who converted many soldiers and was condemned by Diocletian to be shot to death by archers. When they had left him for dead, a Christian widow, Irene, nursed him in her house. After recovering he presented himself before the emperor who immediately ordered him to be beaten to death. His body, thrown into a sewer, was found by another pious woman, whom the saint told in a dream to bury it near the catacombs. His relics are believed to be in the basilica of S. Sebastiano on the Appian Way, which attracted many pilgrims in the Middle Ages. He is frequently represented in art as a beautiful youth wounded by arrows.

See H. Thurston and D. Attwater (eds.), *Butler's Lives of the Saints*, vol. i, pp. 128–130 (1956). (H. C. G.)

SEBASTIAN (1554–1578), king of Portugal from 1557, was born at Lisbon on Jan. 20, 1554, the posthumous son of the heir to the throne John (d. Jan. 2, 1554). He succeeded his grandfather John III in 1557. During his minority the country was governed by the regencies of the widowed queen Catherine (1557–62), a sister of Charles V, and of John III's brother Cardinal Henry (1562–68), who succeeded Sebastian as king of Portugal. The period of the regencies was disturbed by troubles in Portugal's overseas dominions in Morocco, India, and Brazil.

Sebastian assumed personal control in 1568. Fanatically religious from an early age, he also devoted himself to hunting and military exercises, and his sole ambition was to lead a crusade against Morocco. He reversed John III's policy of gradual withdrawal from Morocco and embarked on new conquests. After a preliminary reconnaissance at Ceuta in 1574 he organized a large expeditionary force despite the advice of Philip II of Spain and Cardinal Henry. The army landed at Arzila in July 1578 and at the Battle of the Three Kings near Alcazarquivir on Aug. 4, 1578, sustained a disastrous defeat in which Sebastian was killed. His body was buried at Alcazarquivir, but rumours spread in Portugal that he was still alive. After Spain's conquest of Portugal (1580), Philip II recovered the body in 1582 on payment of a large ransom, but the movement known as Sebastianism grew, its adherents believing that Sebastian would return as the saviour of Portugal. Four pretenders to the throne impersonated him between 1584 and 1598. (DA. A. P.)

SEBASTIANO DEL PIOMBO (SEBASTIANO LUCIANI) (*c.* 1485–1547), Italian painter of the Venetian school who became the friend and protégé of Michelangelo, was born in Venice. According to G. Vasari, who knew him, he was 62 when he died in Rome in 1547, and it is therefore assumed that he was born in 1485. The same authority tells us that he learned "the first rudiments from Giovanni Bellini, at that time an old man. And afterward, when Giorgione had established in that city (Venice) the methods of the modern manner, with its superior harmony and its brilliancy of colouring, Sebastiano left Giovanni and placed himself under Giorgione, with whom he stayed so long that in great measure he acquired his manner." The truth of this statement can be seen in such works as the "Madonna and Child with SS. Catherine and John the Baptist" (Accademia, Venice), the organ doors of S. Bartolomeo a Rialto, Venice, and the altarpiece of S. Giovanni Crisostomo, Venice, recorded by Vasari as having been confused with the work of Giorgione himself. After Giorgione's death in 1510 Sebastiano is said to have finished some of his pictures, and there is a group of paintings whose authorship is still undetermined between them, including such works as the "Adulteress" (Glasgow) and the "Judgment of Solomon" (Bankes collection, Kingston Lacy, Dorset). The "Salome" in the National gallery, London, is dated 1510 and is therefore a key work of this period; Vasari himself once attributed it to Giorgione before realizing his mistake.

Sebastiano perhaps might now have inherited Giorgione's reputation and commissions, but in the spring of 1511 he was invited to Rome by the Sienese banker Agostino Chigi, who had just built the Villa Farnesina by the Tiber and was having it decorated. Sebastiano left Venice and returned only once (1528/29), spending the rest of his life in Rome. His decorations in the Farnesina met with success and he came into contact with Raphael and his pupils, who were also working there, and became his admirer. Later, perhaps quite soon after 1511, Sebastiano transferred his allegiance to Michelangelo and it seems that Michelangelo saw that if he were to correct Sebastiano's draftsmanship, Sebastiano's gifts as a painter were hardly to be equalled in Rome. The first result of this form of collaboration was the "Pietà" (Museo, Viterbo), for which Vasari says Michelangelo supplied "the invention and cartoon," the actual execution being by Sebastiano. The same thing happened with the "Flagellation" painted in oil on the wall of S. Pietro in Montorio, Rome. Michelangelo supplied a drawing for this as early as 1516, although the painting was executed only in 1520–24.

A direct rivalry between two groups came to a head when Cardinal Giulio de' Medici commissioned the "Transfiguration" from Raphael and the "Raising of Lazarus" from Sebastiano. The "Lazarus" (now in the National gallery) was commissioned in 1516 and finished in 1519; Raphael's "Transfiguration" was still unfinished at his death on April 6, 1520. For the next 11 years Sebastiano was reckoned the best painter in Rome, particularly of

portraits, which he produced with less delay than was usual with his other works.

In 1531 Cardinal de' Medici, now Pope Clement VII, gave him the well-paid office of the "piombo" (the supervision of the lead seals attached to papal bulls) and Fra Sebastiano, as he now became, worked less and less. One of his late works (1531 or later) is the "Lady as St. Agatha" in the National gallery. He also invented a method of painting on stone and a technique for painting in oil on plaster walls, and he tried to persuade the pope to make Michelangelo use oil instead of fresco for the "Last Judgment" in the Sistine chapel. This led to a coolness between them which lasted almost to Sebastiano's death, which was on June 21, 1547.

SEBORRHEA: see SKIN, DISEASES OF.

SECCHI, (PIETRO) ANGELO (1818–1878), Italian Jesuit and astrophysicist, noted for his pioneer investigations in solar phenomena and in stellar spectroscopy and spectral classification, was born at Reggio Emilia, Italy, on June 18, 1818. He entered the Society of Jesus in 1833, and became lecturer in physics and mathematics at the Collegio Romano, Rome, in 1839. Driven into exile in 1848 by the proscription of the Jesuits, he went to Stonyhurst college, Eng., and then to Georgetown university, Washington, D.C., where he pursued his mathematical and scientific work, returning to Rome as professor of astronomy and director of the observatory at the Collegio Romano in 1850. Here he erected a new observatory, equipped with a Merz refractor, over the church of Sant' Ignazio, where he carried out his researches into stellar spectroscopy, terrestrial magnetism and meteorology. His meteorograph was demonstrated at the Paris exhibition of 1867.

Secchi's main achievement was his division of stellar spectra into four groups: (1) stars like Sirius, with strong hydrogen lines; (2) stars similar to the sun, with numerous fine lines; (3) stars of the α Herculis type, with nebulous bands degraded toward the red; and (4) carbon stars, with violet-degraded bands. These divisions were subsequently developed into the Harvard classification, based on a simple temperature sequence, that forms the basis of modern systems. Secchi was also active in solar observation; he proved that prominences are appendages of the sun and discovered many features of their behaviour; he also photographed the corona at the eclipse of 1860. He was, in addition, an active observer of double stars. He died at Rome on Feb. 26, 1878.

Secchi wrote *Sulla mesura della base trigonometrica eseguita sulla Via Appia nel 1854–5* (1855); *Catalogo delle stelle di cui si è determinato lo spettro luminoso* (1867); *Sugli spettri prismatici delle stelle fisse* (1868); *Le Soleil* (1870); *Le stelle* (1877).

SECONDARY EDUCATION, a stage in education beyond the elementary (U.S.) or primary (British) level, usually beginning at age 11 or 12 and generally constituting either terminal education or preparation for college—in the United States, high school education. Secondary education constitutes a serious and difficult problem in virtually every country of the world. The difficulties arise from a number of causes: changing demands of modern culture; economic transformation in process everywhere; the ideal of equality of educational opportunity for all; and recruitment and training of young persons of talent to meet the needs and the higher intellectual standards of modern societies. To find a solution for these difficulties involves not only a reorganization of the educational systems of most countries but the abandonment of the monopoly of the traditional concept of secondary education.

This article discusses the background of these difficulties and the emergence and development of systems based on the U.S. common school or single-track plan and the British and European specialized school or multitrack plan, and analyses efforts to provide equality of educational opportunity for all.

For the history of secondary education in various countries *see* EDUCATION, HISTORY OF. For discussion of the organization of secondary education in various national systems of education *see* SCHOOL ADMINISTRATION. *See* also *Education* sections of articles on individual countries.

BACKGROUND OF THE PROBLEM

Classical Curriculum.—This concept can be traced to the grammar and rhetoric schools of Greece and Rome with emphasis on literary training. Expanded into the seven liberal arts the concept was directed to a different aim in the middle ages. The rediscovery of Greek and Latin authors established the predominance of the classical studies in the grammar schools in European countries and then in the American colonies (*see* CLASSICAL EDUCATION). As commercial relations and travel expanded, demands for a type of secondary education to meet new needs were met by the establishment of schools in the 17th and 18th centuries. These schools, however, did not enjoy the prestige of the grammar schools, particularly because they were refused recognition by the universities. Justification for the retention of classical studies, which became meaningless because more attention was paid to form than to content, was that even if they were useless, they trained the mind and the mind so trained could without difficulty attack new situations and problems. The classical curriculum enjoyed a monopoly as the only type of secondary education to the middle of the 19th century. Criticisms were met by an internal reform (neo-humanism) giving more attention to content and meaning, which originated in Germany in the 18th century.

From the early years of the 19th century the traditional classical schools began to enjoy special prestige not only because their graduates were admitted to the universities, but also because they were granted special privileges (*Berechtigungen* in Germany and *sanctions* in France), and in England, after the reforms of Thomas Arnold at Rugby, social recognition as character training institutions. Changing economic and cultural conditions, however, stimulated protests against the monopoly of the classical schools and a demand either for the introduction of modern subjects (foreign languages, sciences, mathematics) or for new types of secondary schools for the teaching of these subjects. By the end of the 19th century different types of curricula (classical, semiclassical and modern) in separate or in the same schools, received equal recognition and privileges. In England, however, publicly maintained secondary schools were not established until after 1902, and the private endowed schools, the best of which were known as "public schools," continued to provide an education which was mainly classical with other subjects grudgingly admitted. The older English universities made Latin and Greek compulsory requirements for admission well into the 20th century. In none of the countries was secondary education for girls provided at public expense until the 19th century, and it was late in that century that opportunities for their admission to universities were provided.

Secondary education constituted a separate type distinct from the elementary schools in all countries except the United States. An insignificant number of pupils passed on from the elementary to the secondary schools, preparation for which was given in different schools (*Vorschulen* in Germany, *classes préparatoires* in France and preparatory schools in England). These schools were fee paying and since their curricula were designed to prepare pupils directly for admission to the secondary schools, the pupils had an advantage over those who wished to transfer from the elementary to the secondary schools. Further, the secondary schools, since they charged tuition, were selective and drew their pupils from the wealthy classes, who could afford to pay the fees and the cost of maintaining their children while at school. Poor pupils of ability might obtain scholarships in competitive examinations, but their attendance usually required some financial sacrifice on the part of parents.

U.S. Common School.—The United States was the first country to provide equality of educational opportunity and to depart from the traditional dual type of organization by adopting the common school system in which elementary and secondary educa-

tion were articulated to facilitate continuous progression through the levels of the system. Some doubt still persisted in the 19th century as to whether the high school grades, in which other than elementary school subjects could be taught, came under the provisions for the establishment of common schools. In 1874, in a court decision on the Kalamazoo (Mich.) case, the provision of secondary education at public expense was declared to be constitutional. Another feature of the U.S. high school was the gradual expansion of the curriculum which included the subjects of the colonial Latin grammar school and the practical subjects of the private academies which emerged during the period of the American Revolution. A new type was the English Classical school established in Boston in 1821. The core of the high school curriculum consisted of subjects required for entrance to college whether by examination or by accreditation, first adopted by the University of Michigan in 1871. The proper content of a secondary education was just as much debated in the United States as in other countries and was defined at the end of the 19th century by the reports of the Committee of Ten (1893) and of the Committee on College Entrance Requirements (1899). It was generally considered that what was good for college entrance was also good for a liberal education.

Expansion of secondary education coincided with increasing urbanization and industrial expansion. Both factors made the provision of high schools possible and higher family incomes enabled parents to keep their children in schools beyond the elementary grades. Two other influences contributed to the spread of opportunities for secondary education for all. The first of these was the investigations conducted early in the 20th century of the doctrine of formal discipline and transfer of training in which it was found that neither developed spontaneously from the study of traditional subjects but could be cultivated under certain conditions. The conclusion was immediately interpreted to justify the provision of any subject that a pupil might request or be interested in. The second influence followed studies of elimination (the number of pupils who left school after a year or two) and of mortality (the number who stayed the course but failed to pass the final examinations). Both investigations resulted in throwing the doors of the high schools wide open for the admission of any subject that pupils, parents or the public demanded. The high school consequently became nonselective and the expansion upward of the universal school was encouraged by leaders who showed a greater interest in keeping pupils in school than in the quality of subjects taught.

The outstanding feature of this system is that pupils pass on normally from the primary to the postprimary school without having to pass entrance examinations or paying tuition. The high school has become the school for all youth, who are not distributed into separate schools but find the courses best adapted to their needs and abilities in the same comprehensive high school with the advice of guidance officials or parents. The weaknesses of the system, which were not recognized until after World War II, are that the high school tended to cater to the average pupils and to ignore those above and below the average; that all subjects were considered to be of equal value educationally under the quantitative system of points and units; and that pupils were not required to stay long enough with any subject to acquire a real mastery. The only requirements that were specifically defined are those necessary for entrance to college.

Dual Plan.—The organization of secondary education in the United States stands out in direct contrast to the educational systems of other countries except the few that adopted the American plan. The characteristic organization outside the United States has been on the dual plan; elementary and secondary education have been distinct types and only a minority of the elementary school pupils passed on to the secondary schools, generally only if they were bright and could win scholarships through a competitive examination. The secondary schools drew their clientele from private preparatory schools. Further the courses in the secondary schools were definite and were limited to the study of the mother tongue and national literature, foreign languages and literature (ancient or modern), mathematics and science, history and geography, some art, music and physical training. The affiliations of the complete secondary schools were with the universities rather than with the elementary schools; pupils who did not complete the full course generally entered white collar rather than manual or technical occupations.

The development of commerce and industry during the 19th century produced a demand for some form of intermediate education, less academic and more practical than the secondary and not as selective. The demand was met in Germany by the creation of *Mittelschulen*, in France of *écoles primaires supérieures* and in England of higher elementary schools and later in some localities of central schools. The curricula of these schools were somewhat more advanced than those of the elementary schools; pupils remained longer and were prepared for employment in business or industry as white collar workers but generally in a lower grade than pupils who came from secondary schools. Through the educational systems a sort of hierarchy was created and the more advanced secondary education was sought frequently for the status and privileges that it conferred. The cleavage between secondary and elementary or postelementary education was maintained by their administration in separate departments of the central authorities. The certificates conferred by different types of schools also contributed to the cleavage, since those of the secondary schools enjoyed higher social and occupational values.

Reform Movements.—This situation continued into the 20th century and gave rise to the reform movements proposed after World War II. In Germany secondary education for boys was provided in nine-year courses in *Gymnasien* where the chief subjects were Latin and Greek; the *Realgymnasien* with Latin and modern subjects; and *Oberrealschulen* with modern subjects. The final examination (*Abiturientenprüfung*) led to a certificate accepted for entrance to a university. Incomplete six-year courses were offered, with the same emphases as in the corresponding complete courses, in *Progymnasien*, *Realprogymnasien* and *Realschulen*. Girls received their secondary education in *Lyzeen* and *Oberlyzeen*. Secondary education in France was provided in *lycées* (state-maintained schools) and *collèges* (municipally maintained); classical, semiclassical and modern courses were available in each school, with special courses in the final or seventh year in philosophy or mathematics. The leaving examination, held in two parts at the ends of the sixth and the seventh years, led to the *baccalauréat*, a prerequisite for university entrance.

Secondary education in England was not provided at public expense until the Education act of 1902 set up local education authorities (L.E.A.s) and permitted them, if of a certain size, to establish and maintain secondary schools. The provision of public secondary education followed Matthew Arnold's plea to "organize your secondary schools" and the report of a commission, with James Bryce as chairman, appointed (1894) to consider "the best methods of establishing a well-organized system of education in England." Undoubtedly the growing competition of Germany exercised some influence in the same direction. Until passage of the act of 1902, secondary education was provided in ancient endowed schools, which included the "great public schools" and many others, day and boarding, which began to be called public schools and a large number of private schools. Many new public schools were established after Thomas Arnold's reform at Rugby. All schools, public and private, charged fees; the majority were boarding schools and their curricula were predominantly classical with instruction in modern languages (including English) and science permitted but not particularly favoured. Their affiliations were with the universities of Oxford and Cambridge, which in the latter part of the 19th century conducted school examinations. Schools were not supervised by any government authority, unless they had endowments to administer. Able pupils from elementary schools could win scholarships in competitive examinations to enter secondary schools at about age 11; normally such schools were day schools since boarding school fees were generally beyond the means of boys coming from elementary schools.

Girls received their secondary education at home or in private schools or schools provided by a voluntary organization such as the Girls' Public Day School trust (1872). Those who completed

their secondary education and passed the necessary examination could enter the few women's colleges in Oxford or Cambridge but could not (until the 20th century) proceed to degrees; others continued their education in one of the provincial universities on an equal footing with men.

The secondary schools established under the Education act were organized on the model of the existing secondary schools. Pupils were admitted by entrance examinations and tuition fees were charged until 1907, when the government regulations required the schools to provide "free places" up to 25% of the enrollment for pupils coming from elementary schools; the free places were subsequently replaced by "special places," the percentage of such places could be from 25% to 50%, and a means test was introduced. The curriculum was designed to provide a general or liberal education, and included English language and literature, at least one foreign language, geography, history, mathematics, science, organized games, physical exercises, music and drawing. Until 1917 the charge was made that the secondary school pupils had to take too many external examinations. In 1917 the number of external examining bodies, normally associated with the universities, was reduced to eight, and under the government's regulations pupils could sit for only two examinations—the first or school certificate, usually taken after four years of secondary education, and the higher school certificate at the end of the course. The certificates were accepted for entrance to the universities.

Patterns of Organization.—The four systems of secondary education—the German, French, English and American—have either influenced the organization of secondary schools directly or are found in other countries. Thus the German type exercised an influence on the types of secondary schools in the Scandinavian countries; French *lycées* were reproduced not only in French-speaking countries but in all the east European and middle east countries, where the French ministry of education often conducted examinations for the *baccalauréat*. English type public schools, boarding schools to meet the needs of a sparse population, were reproduced in Australia and New Zealand, until with the rise of urban centres day secondary or high schools were established similar in aim and curriculum to the local education authorities' schools in England with an emphasis primarily on an academic curriculum leading to university entrance. In New Zealand secondary education in rural areas is provided in district high schools attached to the primary schools; in urban areas two-year intermediate schools have been established leading to the four-year high school. Multipurpose schools are provided in Australia in sparsely populated areas, but in urban centres there exist academic, commercial, technical and home science schools.

In Canada the organization of secondary education varies from province to province; Quebec has replicas of the French and English systems to meet the needs of the different language and religious groups. In the other provinces the majority of pupils attend the publicly maintained schools, which may offer four, five or six year courses, and may be academic only or comprehensive as in the United States. In South Africa there is a common pattern in the fact that secondary education is continuous with primary, extends from standard VI to standard X with examinations at the end of standard VIII in two provinces and a final examination at the end of standard X, accepted for university entrance.

None of the patterns mentioned is found in Latin-American school systems. They have, however, solved one of the serious problems in having an end-on system—the pupils pass on to the secondary schools directly from the primary schools. Secondary education, given in *colegios*, *liceos*, *ginásras* (Brazil) or *institutos de segunda enseñanza* (Cuba), is five or six years in length. Generally the course is divided into two parts or cycles—the first cycle, usually three years in length, is general and common to all, and the second cycle provides for specialization for two or three years in humanities or sciences, depending on the requirements of the faculty that is to be entered in the university. Success in final examinations leads to the *bachillerato* in humanities or sciences. In Chile, a number of experimental schools have been established with courses divided into three parts—a common course of liberal education for all, an exploratory course to discover the pupils' special abilities and interests and a specialized course in humanities or sciences for entrance to the universities.

SECONDARY EDUCATION FOR ALL

World War I marked the beginning of a turning point in the history of secondary education in many countries outside the United States. The basic aim in the new movement was to establish a common system of education founded on the principle of equality of educational opportunity for all. Under various names (*Einheitsschule* in Germany, *école unique* in France and secondary education for all in England) the movement involved the abolition of the traditional dual system (elementary schools for one class of pupils and secondary for a selected group). It also implied a common foundation in education for all at least up to the age of 11 or 12 years. For the time being the term secondary education was not redefined. In Germany, the first step was to abolish the privileged status of the *Vorschulen* and in France the *classes préparatoires* and the same primary education was to be provided for all irrespective of the school that they attended. To enable pupils who did not transfer from the basic school (*Grundschule*) at the normal age of 10, a new type of secondary school (*Aufbauschule*) was established in Germany. In France fees for secondary education began to be abolished in 1931.

In England, following the report on *The Education of the Adolescent* (1926) of the board of education's consultive committee (Sir Henry Hadow, chairman), it was decided that more educational opportunities should be provided and that all pupils should be given some form of postprimary education from the ages of 11 to 15. The age of transfer from the primary to the postprimary stage was thus established at about 11; pupils who did not pass on to a secondary school received a more advanced education in "senior tops" than was previously available in the last three years of the traditional elementary schools. The senior schools, however, continued to be administered by the same department in the central board of education as the primary schools. The raising of the age of compulsory school attendance, recommended by the Hadow committee, was not actually achieved until 1947.

In the United States the problem of the articulation of primary and secondary education had been attacked earlier and for two reasons. It was thought: (1) that the transition from the eighth grade of the elementary school to the first year of the high school was too abrupt; and (2) it was considered desirable to introduce pupils to secondary school subjects slowly and to explore their abilities and aptitudes. One solution was to establish junior high schools to which pupils passed at the age of 12; another was to organize the last two grades of the elementary school as an intermediate section to serve as a gradual introduction to the high schools. The educational organization might be on the 8–4, 6–6 or 6–3–3 basis. In the United States, as in other countries, the end of World War I represented a new stage in educational development. Enrollment in the high schools began to rise rapidly and resulted in serious discussions not only of the aims of secondary education but also of the appropriate subjects to be taught. It had long been obvious that the traditional academic subjects were not suited either to the abilities or the interests of many adolescents. The issue was discussed by numerous committees of which the most influential was the Commission on the Reorganization of Secondary Education which in its 1918 report recommended the following objectives: health, command of fundamental processes, worthy home membership, vocation, civic education, worthy use of leisure and ethical character. These "cardinal principles" did not solve the curriculum problem. The practices varied throughout the country; in some schools various courses were offered; in others programs were tailor made for each pupil according to his abilities and interests. The only requirements that remained specific were subjects prescribed for college entrance with some leeway for electives. Entrance to college could be obtained under the widespread system of accreditation or in the case of private colleges by taking the examinations of the college entrance examination board established in 1899. Outside these requirements for pupils headed for college, the greatest flexibility prevailed and the number of "offerings" in the high

schools increased until a high school certificate meant only that its possessor had spent a certain number of years in the institution or had accumulated 14 to 16 units of miscellaneous subjects.

U.S. Appraisal.—The increasing enrollment in U.S. high schools, attended by about 70% youth between 14 and 18, brought with it a large number of problems, particularly with reference to the content of secondary education. There was at no time any suggestion that a return should be made to selective practices or to separate schools. Criticisms began to be made of the quality of high school achievement. It was stated (*e.g.*, Harvard report *General Education in a Free Society*, 1945) that "the tendency is always to strike a somewhat colourless mean." The Educational Policies commission of the National Education association, on the other hand, based its report *Education for All American Youth* (1944) on the theory that many pupils were not getting an education suited to their abilities, interests and needs and stressed common learnings and vocational preparation for all. At the same time, another group found that of the pupils enrolled in high schools 20% could profit from an academic course, 20% from a technical course and 60% needed quite a different type of education which came to be known as "life-adjustment training" (see *Vitalizing Secondary Education*, U.S. Office of Education Bulletin, no. 3, 1951).

The quality of education became a matter of public concern during and after World War II. Selective service boards had to reject many draftees for illiteracy and physical defects and the armed forces had the task of training many others to the level of functional literacy. The deficiencies of secondary and higher education were revealed when an adequate number of personnel could not be found to fill positions that required a mastery of mathematics, science and foreign languages. Little attention was paid to these revelations until the successful launching of the first sputnik by the U.S.S.R. in 1957 caused a panic throughout the U.S. because of the apparent superiority of the U.S.S.R. in science and technology. Studies were made of the Soviet educational system and groups of educators went to Russia. The general conclusion was that the Soviet system would not be suitable for U.S. education, which would have to be improved internally. Efforts were made in different parts of the country to insist on higher standards of achievement, to require more homework and to set up higher requirements for high school graduation. One aspect that was neglected was the need of teachers with better mastery of special subjects. With the aid of funds from foundations and government agencies, experiments were initiated to improve the courses in mathematics and physics and to provide additional training in summer schools for teachers of these subjects. The emphasis on more science and mathematics was widespread, while inadequate attention was paid to the humanities and social sciences, necessary for a balanced educational program.

Attention was focused on the issue of quality, standards and curriculum by the publication in 1959 of *The American High School Today* by James B. Conant and *Education and Freedom* by Adm. H. Rickover. Conant recommended that all pupils in the comprehensive high schools, irrespective of their special programs, for graduation should be required to study four years of English, three or four years of social studies and at least one year of mathematics and science. For pupils able to profit from an academic course, estimated at 15% to 20%, he advocated four years of foreign languages, four of English, four of mathematics, three of science and three of social studies. Since the small high school is normally unable to provide such a full course, he suggested the establishment of a number of central high schools. Rickover's thesis was that "only massive upgrading of the scholastic standards of our schools will guarantee the future prosperity and freedom of the republic." He urged a program similar to that recommended by Conant and the establishment of special high schools to demonstrate the new program.

It has been generally recognized that the changes taking place after the end of World War II demand better trained manpower and leaders in every aspect of national life—political, social, cultural, economic and scientific and technological—and that a general or basic liberal education should be available for all adolescents. The danger that threatened was a certain imbalance arising from the emphasis on science and technology. The most serious difficulty in implementing the desired reconstruction of secondary education lay in the inadequate supply of well-qualified teachers, caused in part by better paying jobs in other occupations. This situation stimulated plans for the wider use of educational television, programmed instruction and other devices.

Secondary Education in the U.S.S.R.—The educational systems in the Union of Soviet Socialist Republics are organized on the principle of the common or unitary plan with four years of primary school (entered at the age of 7) and three years of junior and three years of senior secondary schools. The incomplete systems consist of seven years, the complete of ten years of schooling, but the rural areas generally have only the four-year primary schools. Secondary education is free and generally coeducational. The curriculum was academic and included: Russian or native language and literature, foreign languages, mathematics, sciences, history, geography, constitution of the U.S.S.R., drawing, singing and physical training, with many hours of homework and stiff examinations, especially at the end of the course. In 1958 the system became subject to criticisms of which Premier Nikita Khrushchev was a leading spokesman. He attacked the emphasis on academic education as unrelated to life and production needs of the country, and particularly because it developed in the pupils a contempt for physical labour. Students who could not gain admission to the universities were unprepared to enter industrial or agricultural occupations. He recommended the academic course for pupils of recognized superior ability, especially in mathematics and science, music or fine arts. The majority should, after seven or eight years of schooling, continue their education in factory vocational schools or work during the day and attend evening schools. Education, following the principle stated by Lenin, should be linked to socially useful labour and production. Ensuing changes added an 11th year to the ten-year system, with polytechnical subjects at all levels and work experience in the last two years. In the mid-1960s the schools returned to the ten-year system with a more orthodox academic program while retaining emphasis on scientific and technical training to produce skilled workers.

Reorganization.—*England.*—The demand for educational reconstruction to provide greater equality of opportunity, raised during World War I, was continued in most of the western European countries and began to be met after World War II. (The postwar changes in the German Federal Republic are given under EDUCATION, HISTORY OF.) The groundwork was laid in England by the White Paper, *Educational Reconstruction*, issued in 1943 by the board of education; and in France by the report of the Langevin commission (*La Réforme de l'Enseignement*, 1946). The recommendations of the White Paper and the report of the Spens committee, *Secondary Education* (1938), were incorporated in the Education act, 1944. Local education authorities were required to provide secondary education for boys and girls above the age of 11, suited to "their different ages, abilities and aptitudes." Three types of schools were proposed—grammar, technical and modern, and combinations of these in multilateral schools. Grammar schools give the traditional academic education; modern schools give a combination of general and practical education, which may include a foreign language; technical secondary schools, still few in number, combine general and technical subjects. Fees have been abolished in publicly maintained schools. Academic or grammar school courses are also provided in direct-grant schools, which receive grants from the government on condition that free places are provided for pupils coming from primary schools, and in independent or private schools, including the public schools. In 1952, the examination system was changed and the general certificate examination was introduced to be taken at about 16 to encourage pupils to stay in school to that age; papers may be taken at ordinary, advanced or scholarship standards. Since the subjects to be taken are not prescribed, modern school pupils began to sit for the examination.

The two chief problems of secondary education in the early 1960s in England centred on (1) the examination by which pupils were allocated to one of the three schools, sometimes referred to

as educational types, and on (2) the separation of pupils into different schools. It was argued that 11 plus could be too early an age to discover the abilities and aptitudes of pupils and that the separation of pupils into different schools was socially divisive. The ministry of education permitted the establishment of comprehensive high schools—about 45, most of them in London and Coventry. The Labour party was strongly in favour of the comprehensive schools (see *Learning to Live: Labor's Policy for Education*, n.d.). The conservative policy was to improve the buildings and equipment of all public secondary schools, to reduce the size of classes and to retain the grammar schools for the ablest children (*see* Ministry of Education, *Secondary Education for All, A New Drive*, 1958).

France.—The system of education in France is being gradually reorganized by decrees; there had been no legislative enactment for reconstruction. The age of compulsory attendance was raised to 14 in 1936. The majority of pupils continue in elementary schools for eight years, of which the last two are practically oriented. At age 12 pupils may take an entrance examination to some form of secondary education: *cours complémentaires*, attached to the primary school and offering a modern or prevocational course; *collèges modernes* (formerly *écoles primaires supérieures*), which provide a general and practical course; *collèges techniques* with academic and technical subjects leading after six years to a new *baccalauréat technique* and to more advanced technical education; and the traditional *lycées* or *collèges*, the former state and the latter municipal institutions. Courses of the *lycées* and *collèges* have been increased, particularly in the second cycle (fifth and sixth years), and provide for a number of different combinations of academic subjects; the first part of the *baccalauréat* is taken at the end of the second cycle. The seventh or last year is devoted to specialization in philosophy–letters, experimental sciences or philosophy–sciences, mathematics or technical and economic sciences. At the end of this year the second part of the *baccalauréat* is taken. Students are no longer admitted to universities on the *baccalauréat* alone but must spend a preliminary propaedeutic or preparatory year in a university and pass another examination before being finally admitted.

Transition.—Secondary education is everywhere passing through a transition stage as a result of 20th-century changes in culture and civilization. The problems that emerge involve a reconsideration of the concept of a liberal education, development of a better understanding of contemporary issues, national and international, and training for adaptability to social and economic changes. In the 19th century the industrial revolution hastened the movement for universal elementary education to produce, among other ends, literate workers. The 20th-century industrial revolution, based on scientific and technological advances, demands more education and is producing occupational redistribution, with prospects of further changes from automation. Redistribution of wealth and the shift of social classes have made the prolongation of education possible. Intensification of nationalism and the consequent economic competition have stressed the importance of well-trained manpower, so that education is being prolonged both in democratic and in communist states. The keynote everywhere is equality of educational opportunity, which brings the problems of allocation according to abilities and aptitudes and of determining the nature of general education for all and the time to begin specialization. *See* ELEMENTARY EDUCATION; COLLEGE; UNIVERSITY; WOMEN'S EDUCATION, HISTORY OF; ADULT EDUCATION; *see* also references under "Secondary Education" in the Index.

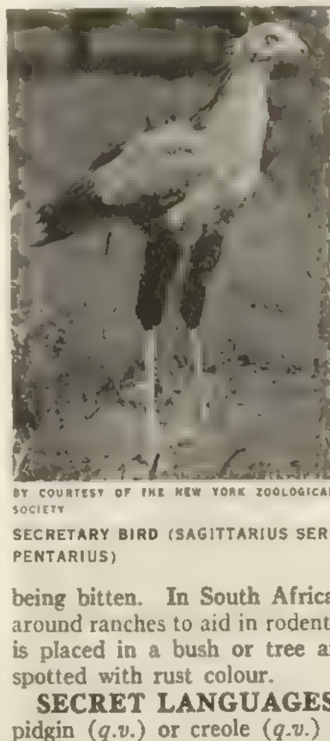
SECONDARY ERA: *see* MESOZOIC ERA.

SECOND BAKU (VTOROYE BAKU) is the popular name for a group of very rich oil fields of the U.S.S.R., lying between the middle Volga and the Urals. These fields have surpassed the old Baku (*q.v.*) oil field as the major source of petroleum in the Soviet Union. The Second Baku lies in the Tatar and Bashkir autonomous republics and the Kuibyshev, Orenburg and Perm *oblasts*. The presence of oil there has been known since the 18th century, but only during the first five-year plans were sufficiently deep bores put down. The first well was at Verkhne-Chusovskiye Gorodki near Perm in 1929, followed by Ishimbai (1932) and Syzran (1935). Since then, production has risen very rapidly from about 6,000 tons in 1929 to about 75,000,000 in 1958.

The Second Baku comprises five major groups of oil fields: (1) the Perm area, with Krasnokamsk as the largest centre; (2) on the Volga near Kuibyshev with Syzran as its centre; (3) the Tuimazy area, with its new oil town of Oktyabrski (since 1955 a new and rich field has been developed close by at Shkapovo); (4) Buguruslan in Orenburg *oblast*; (5) the Belaya valley around Ishimbai and Sterlitamak (*q.v.*). Oil occurs in rocks of Silurian to Permian age, and in general at considerable depth. At Tuimazy, wells reach 9,600 ft.

Natural gas is also found in quantity in the Second Baku, especially in the Buguruslan area. Refining is carried on at a number of centres in each field, notably at Krasnokamsk, Ufa, Sterlitamak and Syzran. (R. A. F.)

SECRETARY BIRD, an African bird with long legs, standing nearly four feet high. Only one species is known definitely, *Sagittarius serpentarius*, constituting the family Sagittariidae. One of the most powerful birds of prey (Falconiformes), it is found locally south of the Sahara. From the back of the head and nape hangs an erectile tuft of long black feathers which reminded early naturalists of a secretary with quill pens in his hair. Around the eyes is orange skin; the head, neck, and back are bluish-gray, the lower surface black; tail quills are banded with black and tipped with white; the beak is hooked.



BY COURTESY OF THE NEW YORK ZOOLOGICAL SOCIETY

SECRETARY BIRD (SAGITTARIUS SERPENTARIUS)

The secretary bird feeds on insects and reptiles and can kill the most venomous snakes, striking them repeatedly with its taloned feet. The long legs together with the bird's habit of leaping back after each stroke preserve it from being bitten. In South Africa it is sometimes tamed and kept around ranches to aid in rodent and snake control The huge nest is placed in a bush or tree and in it are laid two white eggs, spotted with rust colour.

SECRET LANGUAGES. Quite the reverse of a jargon, pidgin (*q.v.*) or creole (*q.v.*) language, each of which serves to broaden communication between groups, a secret language is used by a special group to preserve its identity and to exclude outsiders. Thus the term refers rather to the social function of a speech form than to any property of its structure. The field as a whole is poorly studied, but there are many isolated cases on record. Occasionally, as with Romany (Gypsy) languages and with the Todas in India, a quite distinct language serves the function of secrecy. An imperfectly remembered language, preserved under unusual conditions, may serve ritualistic purposes, as with the west African Lucumí in Cuba.

Most so-called secret languages are grammatically the same as the language of the surrounding community, but consist in systematic substitutions for individual words. In this case it is difficult to distinguish clearly between secret languages in a strict sense and argot, slang (*q.v.*), which uses ephemeral substitutions, and caste, class and technical occupational dialects. Such lexical substitution is recorded among the Sema Nagas and the Langos and among outlaws, thieves, organized criminals, itinerant peddlers and entertainers and religious groups in many parts of the

world. Similar substitutions are used informally by lovers and children. Systematic insertion or substitution of sounds in the normal language of the community is familiar to us as "pig Latin"; analogous practices occur in other western cultures and are elaborately used by Tagalog adolescents in the Philippines.

The principal criterion for application of the term secret language seems to be a concerted effort on the part of the users to exclude others and prevent their acquiring it. By contrast, tabu words are known to a large part of the community, but are by convention not spoken.

SECRET SERVICE, U.S., a bureau of the treasury department, charged by law with the following duties:

1. Protection of the person of the president of the United States and members of his immediate family, the president-elect and the vice-president.

2. Detection and arrest of any person committing any offense against the laws of the United States relating to coins, paper money, checks and securities of the United States and of foreign governments.

3. Detection and arrest of any person violating certain laws relating to the Federal Deposit Insurance corporation, federal land banks, joint-stock land banks and national farm loan associations.

Origin and Early Duties.—Before the American Civil War, the paper currency of the United States consisted of notes issued by banks operating under federal or state charters. As there was no federal paper currency at that time congress left the detection and prosecution of counterfeiters to the states, local authorities and bank associations. The first paper money issued by the U.S. government consisted of noninterest-bearing treasury notes authorized under acts of congress passed in 1861. An 1862 act authorized the issue of "United States notes," popularly referred to as "greenbacks," and the National Bank act of 1863 provided for the issuance of national bank notes (*see* BANKING: *The United States*).

During the Civil War funds were appropriated by congress to suppress the widespread counterfeiting of the currency. The solicitor of the treasury supervised the expenditure of the money appropriated for this purpose; most of the money was used for the payment of rewards to individuals for furnishing information leading to the arrest and conviction of counterfeiters. As this method of operation did not prove to be effective it became necessary to make a definite and centralized effort to suppress counterfeiting and to restore and maintain confidence in the federal currency. Accordingly, in July 1865, Hugh McCulloch, then secretary of the treasury, created the U.S. secret service and appointed William P. Wood as its first chief. Wood had carried out many investigative assignments during the Civil War for the secretary of war, Edwin M. Stanton and was experienced in hunting down counterfeiters. His force at the outset numbered about 30 men. The headquarters office was in Washington, D.C., and field offices were soon established in other cities.

Although the secret service was organized primarily to suppress counterfeiting, other departments of the federal government soon requested the use of secret service agents to investigate violations of many other laws. Since there was then no other general federal law-enforcement agency, it became common practice for the treasury department to loan secret service agents to other government departments to do important investigative work. From 1905 to 1908, by direction of Pres. Theodore Roosevelt, the secret service also investigated extensive land frauds, including those resulting from passage of the Homestead act (1862) which opened lands to settlement. Through dummy entrymen, many cattle barons in the west obtained rich grazing lands intended for homesteaders, and other unscrupulous landowners obtained lands rich in coal, oil and timber by fraudulently claiming them for agricultural purposes. In one such investigation near Durango, Colo., a secret service agent was shot and killed while investigating the suspected theft of coal from government property. The secret service exposed numerous land frauds, recovered millions of acres for the government and prosecuted many influential businessmen and public officials. Following this exposé, congress restricted the work of the secret service to its normal treasury department duties, and several secret service agents were permanently transferred to the department of justice and other government departments to form separate investigative units.

With the outbreak of World War I in 1914, Pres. Woodrow Wilson lifted previous restrictions and directed that the secret service be employed to uncover violations of neutrality. Numerous cases involving espionage and counterespionage were successfully completed by the secret service during the war and its agents worked in close co-operation with the military intelligence services. In the mid-1920s the secret service also investigated the Teapot Dome oil reserve scandals.

Protection of the President.—In 1901 Pres. William McKinley was shot and killed at Buffalo, N.Y., the third president of the United States to meet death at the hands of an assassin. Immediately thereafter, agents of the secret service were assigned to guard Pres. Theodore Roosevelt. In 1913 secret service protection was extended to the person of the president-elect, and in 1917 to the members of the immediate family of the president. Authority to guard the vice-president at his request was given the secret service by act of congress in 1951. During the early decades of the 20th century the secret service also provided protection for foreign rulers who visited the United States until this responsibility was transferred to the security division of the department of state. In carrying out their duty to guard the president secret service agents remain near him at all times and accompany him on all his travels. They went to Panama, for example, with Pres. Theodore Roosevelt, the first president to set foot on foreign soil while in office. Since then, secret service agents have guarded presidents during many historic trips abroad.

While the entire force of the secret service participates to some extent in the protective function, selected special agents known as the White House detail are assigned to stay with the president at all times. Protection of the president involves much more than keeping bodyguards around him; it also entails what is sometimes called "preventive protection." When the president travels, an agent of the White House detail goes in advance to the cities to be visited and joins agents from the secret service field offices nearest to those cities. These men confer with city and state police and other local authorities, determine the safest routes of travel, arrange for temporary residence if the president is to remain overnight and take other steps to provide maximum protection.

When the president rides in an open car through crowded streets, secret service agents walk or ride alongside and keep close watch on the bystanders. These protective measures are supplemented by investigations of persons who threaten the president in letters and other communications. All such communications are carefully analyzed by a group of specialists in what is called the protective research section of the secret service. In spite of these measures, on Nov. 22, 1963, Pres. John F. Kennedy was assassinated while riding in an open car in Dallas, Tex., the first president to meet that fate since the secret service was assigned responsibility for guarding the president in 1901. [The Warren commission report of Sept. 24, 1964, criticized the service's procedures and its inadequate liaison with the F.B.I. and other agencies. In November 1965 the top echelon of the service was reorganized to meet the Warren commission criticisms.]

White House Police Force.—On May 14, 1930, the White House police force, which had been organized in 1922 to protect the executive mansion, executive office and White House grounds, was placed under the supervision and control of the chief of the secret service. Members of the force receive training in the use of revolvers, submachine guns, riot guns, gas grenades, and in the techniques of disarming an opponent. They also receive training in fire fighting and rescue work.

In Nov. 1950 members of the White House police force and secret service agents foiled an attempt by two Puerto Ricans to assassinate Pres. Harry S. Truman, who was then residing at Blair House while the White House was being repaired. One of the

attackers was killed and the other wounded; one White House policeman, Leslie Coffelt, was killed in the struggle and two others were seriously wounded.

Treasury Guard Force.—On July 1, 1937, by direction of the secretary of the treasury, the supervision and control of the treasury guard force was delegated to the chief of the secret service. The treasury guard force protects the main treasury building and annex and a huge quantity of securities in the custody of the treasury department. Members of this force receive training in handling firearms and disarming opponents and in fire protection, alarm systems, first aid and other specialized training.

Other Activities.—The secret service performs a number of services aimed at prevention of counterfeiting and forgery of currency, checks, bonds and other obligations of the U.S. government. These measures include lectures by special agents, exhibits, pamphlets, circulars and an educational film. The secret service has published two informative and educational booklets, *The United States Secret Service, What It Is, What It Does* and *Know Your Money*. *See* also COUNTERFEIT MONEY.

See W. S. Bowen and H. E. Neal, *The United States Secret Service* (1960). (U. E. B.; X.)

SECRET SOCIETIES, any of a large range of membership organizations or associations having secret initiation or other rituals, oaths, grips (handclasps) or other signs of recognition. Elements of secrecy may vary from a mere password to elaborate rituals with a private language and peculiar ceremonials, costumes and symbols. The term may be applied to such widely divergent groups as U.S. college fraternities, the Ku Klux Klan and international Freemasonry as well as to similar phenomena in primitive cultures. For discussion of the latter *see* SECRET SOCIETIES, PRIMITIVE.

Among the earliest secret societies of which historical evidence exists were the oriental mystery cults and the religious mysteries of ancient Egypt, Greece and Rome, which had secret rites, initiations and revelations of still more ancient wisdom (*see* MYSTERY; *see* also MITHRAISM; ORPHEUS; OSIRIS; PYTHAGORAS AND PYTHAGOREANISM). Whereas the mysteries employed secrecy to guard religious truths, other groups have been forced to adopt secrecy to escape or survive suppression and persecution, as in the case of the early Christians in pagan Rome and, in their turn, of various heretical groups in the middle ages (*see* EARLY CHRISTIAN CHURCH; INQUISITION; MANICHAEISM). Medieval guilds (*q.v.*) resorted to solemn initiatory oaths and other elements of secrecy primarily for economic self-protection. Throughout history revolutionary, subversive and conspiratorial groups have organized secretly, as in the case of the Sons of Liberty. The repression of liberal, nationalist and republican movements in Europe in the 19th century, for example, produced an underground network of revolutionary secret societies (*see* EUROPE: *History: The 19th Century, 1815–1914; see* also CARBONARI; CAMORRA). Other examples may be found in the Fenian Irish Republican Brotherhood (*see* FENIANS, AMERICAN; IRELAND: *History*) and the Decembrists or Union of Salvation in Russia (*see* DEKABRISTS). The very existence of secret societies has prompted antagonisms and fostered accusations of immorality, subversion and heresy. Such accusations were made against the Roman mysteries and early in the 14th century were used to justify the ruthless suppression of the Knights Templar (*see* TEMPLARS). The early 19th-century Antimasonic movement in the United States offers another interesting example of opposition to secret societies (*see* ANTIMASONIC PARTY). Many modern secret societies were formed primarily for social and benevolent purposes and to carry out charitable and educational programs: these have been especially numerous in the United States and in the later 19th century attracted large numbers of immigrants who sought companionship and guidance among people who spoke their native language and followed their customs. In many communities such societies in the 20th century have continued to provide the principal means of members' social and civic activities. (*See* FRATERNAL ORGANIZATION; FRATERNITY AND SORORITY.)

With all their diversity of type and origin, secret societies have certain characteristics of structure and function in common and some of their ceremonials reveal surprising similarities. Historic and other details of the more important groups are covered in separate articles under their own names.

Structure and Function.—Secret societies are made up, *ipso facto*, of persons presumably oriented toward similar ends, and these ends usually manifest the characteristic differentiating secret societies from all others—that is to say, the ends are secret. Moreover, admission to membership almost always involves the explicit obligation to preserve such secrecy, and penalties for its violation are likewise explicitly stated. The explicitness involved may sometimes apply only to the members of the society, for secrecy may be so complete that even the existence of some societies is not revealed to outsiders; revolutionary, heretical and similarly subversive secret societies are cases in point. More frequent is partial secrecy: the existence of the society is publicly acknowledged or even proclaimed, as by the Ku Klux Klan (*q.v.*) in the U.S. after the Civil War and again in the 1920s and the 1950s and 1960s; at least some of the ends are made generally known; parts of the society's ceremonial are performed openly; and public co-operation with other groups having fundamentally differing ends may occasionally be undertaken.

But, obviously, secret societies would lose their reason for existence if secrecy were ever entirely abandoned. Many fraternal organizations, for example, maintained the secrecy of their rituals into the second half of the 20th century although, as in the case of college fraternities and sororities, these survived largely as formalities. In most instances, the core of the binding secrecy is to be found in the society's ceremonial. The essential part of this is rarely if ever legitimately known to those who are not initiates, particularly where the really significant ends are concerned. In order to ensure full and exact knowledge of these ends on the part of the initiates, the ceremonial stresses painstakingly accurate repetition and close guardianship. It is often designed to provide a strong emotional appeal, impressing the members with the gravity of the ceremonial occasion and the authenticity of the knowledge thereby revealed. In many secret societies the ceremonial is cast in dramatic form and contains episodes taken from holy books, revered legends, episodes thought to be of crucial historical importance, etc. Oftentimes members play parts enabling portrayal of the origin of the society, and in this portrayal the candidate for initiation usually has a key role. For instance, he may undergo a symbolic journey fraught with obstacles and temptations and at the end thereof receive the "truth" or esoteric wisdom viewed as the society's characteristic possession (*see Ceremonials*, below). In this process physical objects such as keys, pillars, swords, books, globes or staves may be endowed with symbolic meaning, so that their display on later occasions helps to reinstate, psychologically speaking, the awesomeness of the initiatory ceremony.

Many secret societies operate through a system of degrees of progressively higher rank in which secrets are revealed step by step. Initiation is therefore hierarchical; members at the higher levels are more fully aware of the ends pursued by the society than are those at the lower. Consequently, secrets of recognition are graded. That is to say, although there is ordinarily a grip, password, ceremonialized greeting in question and answer form, esoteric phrase, or secret jargon serving many of the purposes of a special language that distinguishes even the lowest initiate from nonmembers, the society has secrets within secrets. Those more fully initiated make every effort, by the use of special names, ordeals or revelations, to set themselves apart, on the one hand, and on the other to stimulate the lower ranks to the effort necessary to reach the exalted degrees.

The sedulous preservation of higher secrets serves several other purposes. For instance, beginning initiates are thereby impressed with the necessity for silence. Not only is this the case, but the art of remaining silent without giving offense to fellow members at lower levels is imparted by direct example. This is especially important when "final truth" and the real ends of the society are known only to those in the more advanced degrees, and even more so when, as in a few societies, the supreme leaders remain unknown to the rank and file membership. An essential technique

in all of this is that secrets remain unwritten, so far as possible; they must therefore be transmitted verbally in a sort of master-pupil situation. Frequently the transmission takes place under striking ceremonial conditions, reinforced by oaths of allegiance coupled with detailed specifications of dire punishment for traitors. In many modern secret societies such punishment seldom if ever occurs, but there have been instances of rigidly enforced discipline, especially in societies of subversive type—and some modern secret societies, in their early stages, were regarded as subversive.

The effects of secrecy on personality are many, but among them may be listed the growth of a sense of fusion, of a "mystic tie," induced by the sharing of secrets under the appropriate ceremonial circumstances. Further, the appropriately initiated person may effectively acquire norms or standards that extend or even substitute for the norms of the larger society of which he is apparently an integral part. Some secret societies, indeed, lay claim to the total personality of the fully devoted member, but this claim is virtually impossible of fulfillment.

Even though not fulfilled, however, the claim to the total personality means that sharp distinctions may be drawn between members and nonmembers, or in-groups and out-groups; some secret societies, even when their ends are not overtly subversive, may therefore operate in ways such that they tend to split larger societies. This being the case, supporters of various institutions within the larger society may become quite antagonistic to secret societies in general, resulting in accusations of overtly traitorous, heretical, immoral or similarly unworthy ends and their accompanying ceremonials. Political antagonism to secret societies has of course been much in evidence under totalitarian regimes—Nazi, Fascist and Communist—where all groups not controlled by the state are suppressed to the greatest possible extent.

Where secret societies effectively co-ordinate with the larger societies of which they are parts, as is often the case, the co-ordination is frequently linked with class affiliation. Secret societies recruited from the upper classes are more prone to support the existing social order than radically to challenge it; at most they aim at the "moral regeneration" of the larger society. Secret societies drawn from the ranks of the disaffected, however, are seldom free from subversive intentions and may become drastically revolutionary, heretical or even criminal, as the Mafia and the Molly Maguires (*qq.v.*).

An astonishing number of secret societies, when thoroughly investigated, can be shown to have ceremonials testifying to common origins or, at the very least, remote historical connections. At the same time, some secret societies bearing the same name and practicing the same ceremonial, in all essentials, show striking variations from one country to another (*see* ROSICRUCIANISM). (HD. BR.; J. K. RH.)

Ceremonials.—The following account of the ceremonials of the ancient Chinese Hung or Triad society by Freemason historian J. S. M. Ward indicates some of the similarities in the ceremonials of different groups.

The Hung society of China was founded, or perhaps reorganized, in A.D. 386 by the Buddhist patriarch Eon or Hwui-Yin, to spread the cult of Amitabha Buddha. Contemporary with the ancient mysteries and itself a great mystery rite, it survived over 1,500 years. The Hung rituals as they evolved showed a blending of Taoist-Buddhist ideas having curious analogies with the Egyptian *Book of the Dead*, and with certain "higher degrees" in western Freemasonry. The ceremony symbolized the journey of the soul through the Underworld and Paradise to the Holy City of the Gods, called the City of Willows, and interwoven with this was an allegory of the experiences of the mystic in his quest for union with the Supreme Being. As regards its analogies with Masonry, practically every important incident is found in certain higher degrees in England and America, while most of the hand signs are known to many Freemasons.

The ceremony comprised four sections. First the traditional history was given to the candidates in the anteroom before they entered the lodge. It was a moving story, wherein a body of monks who had helped the emperor were requited by him with the foulest treachery, all being murdered save five, who became the founders of the order. There were three villains, and for political purposes one was a Manchu emperor, either Khang Hsi, or, in some versions, his son, but originally the story was allegorical.

After this the candidates were "prepared" in the anteroom. The most notable incidents were (1) ceremonial washing and changing into white robes to symbolize not only mourning but that they themselves were dead; (2) the right arm, shoulder and breast, and also the left knee, were made bare; and (3) grass slippers were substituted for ordinary boots. Meanwhile the master opened and consecrated the lodge and invested his officers.

The third section dealt with the actual admission of the candidates, who had to pass through three gates inside the lodge and take the oath of blood brotherhood by mingling their blood with that of all members present in a cup of wine, from which each person present drank. (Women as well as men were eligible.)

The last section consisted of a catechism; the master asked a series of questions, which the conductor answered for the candidates. These revealed that they had been on a long and mysterious journey, first by land and then by boat, till they reached the City of Willows. Throughout the whole of this part of the ceremony great stress was laid on numbers, which had a definite mystical significance. The triangle also played an important part in the ritual, hence the name "Triad" society. The brotherhood had many aliases, the most famous being "The Society of Heaven and Earth." The significance of the ceremony was revealed by the opening questions:

> Master: Whence come you?
> Vanguard: From the East.
> Master: At what time?
> Vanguard: At sunrise, when the East was light.

See FREEMASONRY; *see* also references under "Secret Societies" in the Index.

See J. S. M. Ward and W. G. Stirling, ***The Hung Society***, 3 vol. (1925–26). (J. S. M. W.)

SECRET SOCIETIES, PRIMITIVE, a term loosely applied to a medley of associations (in nonliterate societies) which have little in common beyond an element of secrecy. It can be applied to the secret cabals of witches and warlocks, *e.g.*, the Mbatsav of the Tiv (*q.v.*) in Nigeria, which exist only in the minds of the more impressionable members of the community, or to such secret organizations of criminals or revolutionaries as the famed Leopard society of Sierra Leone or the Mau Mau of Kenya (*q.v.*) where the secrecy relates primarily to the membership of the association which is known only to the superior officers of the society. The most common reference, however, is to those societies or clubs in which membership conveys enhanced social status and the secrecy relates only to portions of the rituals. Secret societies of this sort form part of a wider category of associations which R. H. Lowie has called sodalities and which includes feasting clubs, dramatic and recreational societies, religious fraternities, professional unions of doctors, diviners and other specialists, initiation schools, associations of titled chiefs like the "palace societies" of Benin (*q.v.*) or the Ozo societies of the Ibo (*q.v.*) of Nigeria, associations of warriors like the military societies of the Plains Indians of North America and the head-hunting societies of west Africa or of southeastern Asia, and mutual aid societies which range from the Chinese tongs of Malaya to the tribal and patriotic unions of Nigeria and the native brotherhoods of North America.

The theories put forward by H. Webster, H. Schurtz and L. Frobenius about the origin and development of secret societies and other sodalities from associations based on the solidarity of persons of the same sex and age, and by W. H. R. Rivers and F. W. Butt-Thompson about their diffusion in Melanesia and west Africa were no longer accepted by anthropologists in the 1960s. No satisfactory classification or definitive terminology has been formulated because many of the varied functions these associations perform are complementary and interchangeable. Some ethnographers apply the term secret society to any associations which manifest some element of secrecy, while others prefer to

avoid it altogether; however, when the term is retained, usually it is limited to a more specific type of association whose primary function is the performance of rituals, the mysteries of which are known only to initiates. The society is represented to the uninitiated as an organization which can control a particular supernatural force or being, in most cases a nature spirit or spirits or the ancestral ghosts of the community. The well-being of the community is believed to be dependent on the propitiation of this supernatural power. The society thus is able to discipline the community in its name. Meetings, sometimes in secret places, may not be attended by the uninitiated under severe penalties, though they are allowed to hear the mysterious noises which may emanate from the participants. The society also provides periodic public spectacles of pageantry and dancing in which the spirits to which it ministers are represented by some of its members, usually with their identity concealed by masks or other disguises.

Secret societies of this type and the masks and other sculpture associated with them reached a very high degree of sophistication among the Northwest Coast American Indians and in parts of west and central Africa and of Melanesia (*see* MASK). The world-wide distribution of these societies cannot be explained in terms of diffusion from any particular centre; it is uneven and erratic, and even in such regions as west Africa where these societies are very prominent there are areas (notably in Ghana) where they are conspicuous by their absence.

Secret societies may be exclusive or inclusive in their membership. In some cases they are limited to a few ritual specialists and wealthy men, in others (*e.g.*, among the Kwakiutl of British Columbia) they extend to all adult and near-adult men and women who can claim to belong to the tribe by right of descent or marriage. In general, however, membership is confined to the adult men of the community (*e.g.*, the Ekpo society of the Ibibio) and although among the Mende and adjacent tribes of Sierra Leone and Liberia the women have their own secret societies (*e.g.*, the Bundu society), women and children are usually regarded as the uninitiated and profane section of the community. As boys approach manhood they are initiated into the sacred mysteries the men control.

In some communities the men are organized as a single society with a number of subdivisions or grades, according to the size of the community. The grading may be based purely on age, as among the Murngin of Australia where a man as he matures progresses through a succession of grades each with its own special mysteries into which he is initiated (*see* AGE SET). Grading also can be based on technical efficiency as in the Sekiapu society of the Kalabari of Nigeria, which performs a seven-year cycle of masked plays and grades members as those who are learning the plays, those who are performing the current cycle and those who have completed their cycle. Where wealth is unevenly distributed in a community, it may replace age as the essential criterion, and the gifts and feasts required for admission into the superior grades are sufficient to exclude all but the richest members of the society.

Where there is a single or dominant secret society it frequently acquires political functions, particularly in communities which lack strong chiefs and other centralized forms of government. Here the society forms a powerful focus of unity as it brings together in a single, self-disciplining association all the men of importance in the community without regard to their clan or lineage affiliations. It provides them with a forum for political discussion and negotiation of other business in a private, uncontroversial atmosphere freed from the tensions of interclan and intersectional rivalries which characterize the village councils and other public meetings. Thus such secret societies as the Ogboni of the Yoruba (*q.v.*) of Nigeria or the Harihu of the Elema tribes of the Papuan gulf, though they may not be represented in the formal government councils and moots of their community, are the real power behind them; they enforce the decisions of these councils. Because it can enforce its authority such a secret society also tends to become a judicial tribunal for the settlement of disputes and for the arrest, trial and punishment of criminals. So effective were some of these societies in their political and judicial functions that in some cases, notably in the west African port of Old Calabar in the 19th century, the Ekpe secret society had taken over all the functions of government. The two kings were the head and deputy head of the society and with other members of its highest grade (*nyamkpe*) formed the legislative and executive council of the community as well as its supreme court. The members of the second highest grade of Okpoho (Brass) Ekpe enforced obedience to their laws and decisions using as their agents and executioners junior members of the society disguised as the attendant spirits of Ekpe, the forest demon, to whom the society ministered.

While some communities have single, all-purpose societies of this type, others distribute political, ritual, educational and other public duties between a number of different societies, some of them secret as here defined. In some cases (*e.g.*, among some Yoruba, Ibibio, Ibo or Yakö communities of Nigeria) there is one, sometimes more than one, inclusive secret society into which almost all the men of the community are initiated and which is responsible for the masked plays and other public pageantry and dancing; there are also a number of more exclusive societies (each with special social duties) which are joined by the more socially ambitious men as they rise in the social scale; and there is one dominant and exclusive society with membership confined to the leading men of the community. In other cases no society is supreme and political; ritual and other authority is divided among a number of societies co-ordinated in a complex ceremonial organization. Among the American Indian tribes of the northwest coast the principal objective of these ceremonies is the validation of social status, in particular that of chiefs; among the Pueblo Indians (*q.v.*) of the southwestern U.S. it is the fertility of crops and the control of cosmic forces on which this fertility depends. Among the Santo Domingo Pueblo the ritual business of the community is distributed among 14 societies, 10 of them secret in the wider sense in that each has its own secret rituals relating to particular activities (one being concerned with war, one with hunting magic and the others with curing specific diseases) and 4 of them secret in the narrower sense that they are responsible for the kachina (ancestor) cult and the masked dances associated with it. All members of the Pueblo are grouped into two of these secret societies (Turquoise and Squash), each with its own kiva (underground lodge) and kachina cult into which only the men are initiated. Each kiva is associated with a more exclusive secret society named respectively Koshaire and Quirana after the particular ghosts or spirits to which it ministers. All these four societies are involved in private and public rituals designed to produce rain and to control the movements of the sun while the kachina rituals of the secret societies are intended to secure the intervention of the tribal ancestors for the same purpose. For a discussion of similar associations in less primitive cultures *see* SECRET SOCIETIES.

SECULAR GAMES were celebrated at Rome to mark the commencement of a new saeculum, or generation. It is important to note that there was a *saeculum civile*, the length of which was definitely fixed at 100 years, and a *saeculum naturale*, which, under Greek and Etruscan influence, came to be accepted by the quindecimviri as 110 years. According to tradition the secular games (*Ludi Saeculares*, originally *Terentini*) had their origin in

certain sacrificial rites of the gens Valeria, which were performed at the Terentum, a volcanic cleft in the Campus Martius. According to the Roman antiquarians themselves, they were derived from the Etruscans, who, at the end of a mean period of 100 years (as representing the longest human life in a generation), presented to the underworld deities an expiatory offering on behalf of the coming generation. The first definitely attested celebration of the games took place in 249 B.C., on which occasion a vow was made that they should be repeated every 100th year (their name being also changed to *Saeculares*), a regulation that seems to have been immediately disregarded, for they were next held in 146 (not 149, although the authorities are not unanimous); in 49 the civil wars prevented any celebration. They would probably have fallen entirely into oblivion had not Augustus revived them in 17 B.C. In explanation of the selection of this year, it is supposed that the quindecimviri invented celebrations for the years 456, 346, 236, 126, the saeculum being taken as lasting 110 years.

In later times various modes of reckoning were adopted. The dates were: A.D. 47 (under Claudius), celebrating the 800th year of the foundation of the city; 88 (under Domitian), an interval of only 105 instead of 110 years; 147 (under Antoninus Pius), the 900th year of the city; 204 (under Septimius Severus), exactly two saecula (220 years) after the Augustan celebration; 248 (under Philip the Arab), the 1,000th year of the city; 262 (under Gallienus), probably a special ceremony in time of calamity. In 304 (which should have been 314) Maximian intended to hold a celebration but does not appear to have done so. From this time nothing more is heard of the secular games until revived in 1300 as the papal jubilees instituted by Boniface VIII.

At the beginning of the harvest, heralds went around and summoned the people to the festival. The quindecimviri distributed to all free citizens on the Capitol and in the temple of Apollo on the Palatine various means of expiation—torches, sulfur and bitumen. There, and in the temple of Diana on the Aventine, wheat, barley and beans were distributed, to serve as an offering of first fruits.

The festival then began, at which offerings were made to various deities for three days and nights. On the first night the emperor sacrificed three rams to the Parcae at an underground altar on the banks of the Tiber, while the people lighted torches and sang a special hymn. On the same or following nights, a black boar and a black sow were sacrificed to Tellus, and dark victims to Dis (Pluto) and Proserpine. On the first day white bulls and a white cow were offered to Jupiter and Juno on the Capitol, after which scenic games were held in honour of Apollo and Diana.

On the second day noble matrons sang supplicatory hymns to Juno on the Capitol; on the third, white oxen were sacrificed to Apollo, and 27 boys and maidens sang the "secular hymn" in the temple dedicated to him by Augustus on the Palatine.

Originally the gods of the underworld had been the objects of the ceremony. The introduction of Apollo, Diana and Leto was attributable to Augustus, for whom they had become patron deities; hence their imposing position in the rites and in the *Carmen Saeculare* of Horace, written for the festival of 17 B.C. and still surviving.

BIBLIOGRAPHY.—The above particulars are from Zosimus (vol. ii, pp. 5–6, which contain the Sibylline oracle), who, with Censorinus (*De Die Natali*, 17), Valerius Maximus (vol. ii, p. 4) and Horace, is the chief ancient authority. The inscription commemorating the ludi of 17 B.C., discovered in 1890, relates in fragmentary form the details of the festival and preserves some of the expiatory prayers. It is printed in the *Ephemeris epigraphica*, vol. viii, with a full commentary by Mommsen. *See* also M. Warde-Fowler, *Roman Essays*, pp. 111–126 (1920); J. Gagé, *Recherches sur les jeux séculaires* (1934); H. Wagenvoort in *Studies in Roman Literature, Culture and Religion*, pp. 193–232 (1956); and the classical dictionaries and encyclopaedias. (T. V. B.)

SECULAR INSTITUTE, in the Roman Catholic Church, is a society whose members profess the evangelical counsels in the world in order to attain Christian perfection and the full exercise of the apostolate. Secular institutes were given papal approval in 1947 by the apostolic constitution of Pius XII, *Provida Mater Ecclesia*, further confirmation and explanation by his *motu proprio Primo Feliciter*, and juridical directives for establishment by the instruction *Cum Sanctissimus Dominus*. The approval of this new form of the Christian state of perfection was the result of a long historical development. The Gospel records the invitation to adopt permanently a more perfect way of life by the practice of poverty, chastity or celibacy, and obedience. The historical forms of responding to this vocation in societies ("institutes" in canon law) approved by the church and erected in the juridical "states of perfection" are: orders and congregations, in which the counsels are professed by public vows and life in community; societies of common life without public vows; and now secular institutes without public vows, required common life or distinctive garb. Members of the latter pursue personal Christian perfection and the apostolate while living "in and of the world." Subject to the Sacred Congregation of Religious, a secular institute may be clerical or lay or mixed, and may adopt a diocesan or interdiocesan form. Among the major secular institutes are Missionaries of the Kingship of Christ (priests, men, women); Opus Dei (priests, men, women); Caritas Christi (women); Society of the Heart of Jesus (priests); Our Lady of the Way (women). For a list of secular institutes of men, *see* ORDERS AND CONGREGATIONS, RELIGIOUS.

Haley (ed.), *Apostolic Sanctity in the World* (1957); *De Institutis saecularibus* (1951); J. M. Perrin, *Secular Institutes* (1961). (J. E. HA.)

SECUNDERABAD, a town and cantonment of Hyderabad district in Andhra Pradesh, India, now administratively forming part of Hyderabad city. The town was one of the largest cantonments in India during the British regime. Its area when handed over by the British on Dec. 1, 1945, was 3.6 sq.mi. but had more than doubled by the 1961 census, when its population was 187,471. There are some fine old buildings including St. John's church and St. Mary's cathedral (erected in 1847). St. Joseph's orphanage with a school, opened in 1856 and run by Loreto nuns until 1889, is managed by the nuns of St. Ann's convent. The town is still a stronghold of Christian missionary endeavour and education. The large and well-equipped King Edward VII Memorial hospital was renamed Mahatma Gandhi hospital. Founded in the name of Sikander Jah (Asaf Jah III) in 1806, Secunderabad is a junction on the Central railway and a centre of wholesale trade and commerce. *See* also HYDERABAD. (S. AH.)

SECURITIES REGULATION, a term commonly used to designate legislation designed to protect the investing public from misrepresentation in the sale of stocks, bonds, and other negotiable instruments.

Until the close of the 17th century, most industries and businesses were financed by the same persons who managed them. The Industrial Revolution, however, with its complex enterprises requiring more capital than could be contributed by few individuals, led to the formation of British and American companies for which necessary funds could be obtained only from the public. To protect investors against sharp practices used by some company promoters, legislation was enacted in both countries.

United States.—Although various statutory and constitutional provisions affecting sales of securities were enacted by the states beginning about 1850, Kansas, in 1911, adopted the first comprehensive "blue-sky law," so-called because it was directed at speculative schemes that "had no more basis than so many feet of blue sky." By 1917 the constitutionality of such regulation had been upheld by the U.S. Supreme Court, and by 1933 every state except Nevada had a blue-sky law.

State regulation is classifiable into three types, with most state systems constituting a combination of all three:

1. *Antifraud statutes.*—These statutes expand the usual definition of "fraud" in ordinary commercial transactions by declaring various unfair securities sales practices actionable by private suit, criminal penalty, or injunction. One important expansion is the inclusion of half-truths, promises without basis, and omissions or concealments of material facts within the definition of fraud in a securities transaction.

2. *Broker-dealer registration.*—Many states require registration and the filing of periodic reports by all brokers and dealers in securities, who must furnish in an application for registration evi-

dence of the financial responsibility and good repute of the applicant. Some states require that an independent audit of the registrant be made and reported annually. Most states outlaw "bucket shop" operations, whereby a broker anticipating a price decline would "bucket" a customer's purchase order instead of executing it and would thereby gamble on making a secret profit after purchasing at a lower price. The common requirement that specific confirmation slips be sent to all customers is aimed at "bucketing." Provisions in many states also require separate registration of each securities salesman.

3. *Securities registration.*—About 40 states have some requirement for registering each individual issuance of securities. Most states permit nonexempt securities—usually those of well-established companies traded on a national exchange or already registered under federal law—to be registered by mere notification to the state agency. Otherwise, securities must be the subject of a detailed registration statement disclosing the history and business of the issuer; names, addresses, and compensation of officers, directors, and large shareholders; the underwriting and promotional arrangements; and other information from which the security may be evaluated. Certified financial statements and the principal corporate documents governing legal organization and structure must be furnished with the registration statement. Many states also regulate the character and content of any prospectus or other advertising material used to solicit sales. Among the practices at which these provisions were aimed was the transfer of property, such as mining claims, patents, and other undeveloped assets, of speculative, unproved, or fictitious value, for securities having a face or market value equal to the inflated value of the assets. Such securities, sometimes called watered stock because not backed by solid asset value, would then be sold to the public without adequate disclosure of the background.

While many state statutes undertake no more than a full disclosure, on the theory that the government interest is limited to protecting investors against purchasing securities which they have no opportunity to evaluate, a few states, notably California, give the securities commissioner or other agencies power to prohibit the sale of securities deemed by the commissioner to be unfair or inequitable. These states usually issue rules indicating what promotional arrangements, in the form of compensation, share options or bonuses, will be considered so unduly favourable to the promoters and unfair to the public as to preclude sales within the state or require protective orders, such as holding promoters' shares in escrow until the company is successfully established.

Exemptions and exceptions in state statutes normally include small issues, variously defined as issues offered to less than 10 to 25 persons, or in the amount of $25,000, and for private offerings to institutional or other investors.

In 1956 a Uniform Securities Act containing all three types of state securities regulation was proposed by the National Conference of Commissioners on Uniform State Laws. It is a disclosure-type proposal and includes provisions whereby state regulations may be more closely coordinated with federal registration procedures. At least ten states adopted statutes modeled substantially after the Uniform Act in the first four years after its promulgation.

Federal securities regulation first came in the wake of the 1929–32 stock market decline. The Securities Act of 1933 required that all nonexempt securities be registered with the government and that the registration statement disclose all material facts about the issuer and the issuance. A prospectus, filed as part of the registration statement, must be furnished to all purchasers prior to sale or upon delivery of the securities. A proposed registration statement prepared by the issuer is reviewed by government lawyers and accountants, who frequently suggest revisions necessary to put it in form to be effective. No sale may be made until the statement is effective, and prospectuses may not be used except in the form approved by the government.

The principal exemptions from the registration process are for government securities, securities of charitable and similar nonprofit organizations, securities sold only intrastate, private offerings, and issuances of less than $300,000, for which a short-form notification procedure is provided. The small business exemption may, however, be withheld if there is inadequate disclosure of certain facts in the notification procedure.

Under the Securities Exchange Act of 1934, which created the Securities and Exchange Commission (SEC) to administer federal securities regulation, all securities exchanges must be registered with the SEC, and before shares are traded on the exchanges registration statements must be filed with the exchanges and the SEC. The act contains provisions governing a variety of practices, such as short-selling, floor trading, concerted buying and selling for the purpose of artificially manipulating prices, hypothecation of customer's accounts, and short-swing (within six months) "insider" trading in shares of a corporation by its officers, directors, and large shareholders. Brokers and dealers must register with the SEC, and supervision of their activities is carried out by the National Association of Securities Dealers, a private body which must be registered with the SEC and through which disciplinary action of its members is taken in accordance with SEC findings.

The 1934 act also gives the SEC broad rule-making powers, which it has exercised, to penalize fraud, as broadly defined in the statute and rules, in sales made by mail or in interstate commerce; to require that periodic reports be made to shareholders and filed with the SEC by corporations listed on exchanges; and to supervise the solicitation of proxies of securities listed on exchanges. Under its antifraud rules the SEC also undertakes to curb the activities of "boiler room operators," a term applied to organizations of securities salesmen using high-pressure sales tactics by telephone. The jurisdiction of the SEC over proxy solicitation, reporting, and "insider" trading as to listed companies was greatly expanded by the Securities Act Amendments of 1964 to include, after 1966, all corporations having assets of more than $1,000,000 and 500 or more shareholders.

Great Britain.—The regulation of securities in Great Britain began in the 19th century with enactment in 1844 of the British Companies Act requiring registration of company prospectuses. By mid-20th century it was largely governed by the Prevention of Frauds (Investment) Act, 1958, and the Companies Act, 1948. The Investment Act permits only members of a recognized stock exchange, dealers licensed by the board of trade, or exempted persons (such as banks, insurance companies, and issuing houses) to deal in securities. The activities of the former two are tightly regulated by the stock exchanges and the board of trade, respectively. The act also makes it a criminal offense to induce investment by the knowing or reckless use of misleading, false, or dishonest statements or the dishonest concealment of material facts. The act further prohibits the circulation of any written invitation to subscribe for, buy, or sell any securities, unless it is: (1) made through a permitted dealer; (2) approved by the board of trade; (3) made by a company only to its own shareholders, or (4) accompanied by a prospectus complying with the Companies Act.

The Companies Act requires every written invitation to the public to subscribe for or purchase shares made by a company, or by an issuing house which markets the issue, to be made in the form of a prospectus containing matters specified in the act. Copies of this prospectus must accompany all application forms sent to prospective investors. The prospectus must reveal full details of the promotion arrangements and the company's history and business, director, and promoters, capital structure, financial results for the past five years, certified by its auditors, and all important contracts entered into during the previous two years. Little, however, need be disclosed when the company makes a "rights issue" (in which existing shareholders are offered the opportunity to take up further shares), which is now the usual method used in England by an established company to raise additional equity capital.

An investor induced to subscribe for shares by misrepresentations in the prospectus may repudiate his subscription contract and claim the return of any money paid; or sue the directors for damages for deceit if he can prove fraud; or sue the promoters, directors, or the issuing house for compensation for any loss. Certain criminal penalties may also be imposed.

The prospectus must be filed with the registrar of companies, but this official does not check the accuracy of its contents nor does he comment on the merits of the company or of the investment. This absence of surveillance, however, has not generally resulted in abuses. The realities of corporate financing require, first, that the shares be traded on one of the stock exchanges, usually the London Stock Exchange, and, secondly, that they be offered to the public through an issuing house. Compliance with prospectus regulations of the stock exchanges, and the thorough investigation made by the issuing house of all aspects of the company and of the issue, together generally ensure that the public is invited to invest only in reasonably sound ventures. *See* also Stock Exchange.

SEDAINE, MICHEL JEAN (1719–1797), French dramatist who played an important part in the development of both light opera and drama, was born in Paris, June 2, 1719. Sedaine, a mason's labourer turned architect, was self-educated. He began by writing songs and poems, *Poésies fugitives* (1752), then turned to light opera with *Le Diable à quatre* (1756). He collaborated first with the musician François Philidor in *Blaise le savatier* (1759), etc., then in a more serious vein with Pierre Monsigny, gaining a signal success with *Rose et Colas* (1764). Sedaine's collaboration with André Grétry in *Aucassin et Nicolette* (1779; Paris, 1780), *Amphitryon* (1786; Paris, 1788) and *Guillaume Tell* (1791) brought light opera nearer still to opera and serious drama. Their best work, *Richard-Coeur-de-Lion* (1784) ensured Sedaine's election to the Académie Francaise (1786). Sedaine's *Le Philosophe sans le savoir* (1765) is important in dramatic history because, though entitled a "comedy," it is the best example of the *drame bourgeois,* which Diderot had expounded some years earlier. The play defends the businessman who is also a man of honour like any noble. *La Gageure imprévue,* a lively one-act play, followed in 1768, but censorship held up the performance of *Maillard,* a prose tragedy, and *Raymond V,* until 1788 and 1789. Sedaine died in Paris, May 17, 1797.

See L. Gunther, *L'Oeuvre dramatique de Sedaine* (1908); L. P. Arnoldson, *Sedaine et les musiciens de son temps* (1934). (D. Ks.)

SEDALIA, a city of west-central Missouri, U.S., about midway between Kansas City and Jefferson City; the seat of Pettis county. It was established in 1860 and was chartered in 1889. It became the western terminus of the Missouri Pacific railroad until after the American Civil War and was an important railhead for the Texas cattle drive of 1866. Later the Missouri-Kansas-Texas railroad built through Sedalia and large railroad shops became its most important industry. The city is a thriving agricultural shipping and distributing centre. Industries are diversified, including flour mills, ice and poultry-packing plants, and firms manufacturing glass blocks, trailers and prefabricated houses. Whiteman air force base is nearby. Missouri's state fair is held in Sedalia annually in August. During the Civil War the city was a Union post except for a one-day raid by Sterling Price. Generals Nathaniel Lyon and John C. Frémont outfitted forces there in 1861. For comparative population figures *see* table in Missouri: *Population.* (Jo. L. H.)

SEDAN, a town of northeastern France in the *département* of Ardennes, lies on the Meuse river 12 mi. (19 km.) by rail E.S.E. of Mézières. Pop. (1962) 20,261.

The old town is situated on the right bank of the river and in spite of many wars still has some old buildings, including a 15th-century castle locally claimed as the biggest in Europe. The Place Turenne contains a statue of the great soldier born in Sedan, the marshal de Turenne. South of it is the Place Goulden with its gateway separating the old town from the later additions, and the Avenue du Général Leclerc lined entirely with buildings erected since World War II. Other features are the town's oldest building (1 Rue du Ménil) which houses the museum, St. Charles' church (begun in 1593, severely damaged in 1940), the Dijonval or old royal serge factory and the botanical gardens. Across the river is the industrial suburb of Torcy.

Sedan has woolen, metallurgical, chemical and electrical industries; a factory making steel pipes employs about 1,700 workers. There are good road and rail connections and heavy freight is carried on the Meuse.

In the 14th century Sedan was a dependency of the abbey of Mouzon. United to the French crown by Charles V, it was ceded by Charles VI to Guillaume de Braquemont. Guillaume's son Louis sold it in 1424 to his brother-in-law, Évrard II de La Marck (d. 1440), who began the fortification of the town. Robert I, lord of Sedan (d. 1487), became chatelain of Bouillon in 1482. Robert IV (d. 1556), marshal of France, styled himself duc de Bouillon and was recognized as sovereign in Sedan. His son Henri Robert (d. 1574) was designated prince of Sedan. He publicly professed Calvinism and henceforth Sedan became a Protestant centre. Charlotte, the last La Marck sovereign of Sedan, married, in 1591, Henri de La Tour d'Auvergne, vicomte de Turenne (1555–1623). He and his successor, Frédéric Maurice (1605–52), conspired against the French government, to which Sedan was finally lost in 1642. (*See* also Bouillon.)

Battle of Sedan, 1870.—The battle of Sept. 1, 1870, in the Franco-German War, led to the overthrow of the French second empire. The French army under Marshal M. E. de MacMahon should have retreated toward Metz to relieve the other French army there under Marshal Achille Bazaine. On Aug. 31 MacMahon assembled his forces in and around Sedan to face the German 3rd and Meuse armies under the princes Frederick William of Prussia and Albert of Saxony, who approached from opposite sides to carry out an encircling movement, successfully cutting off the French lines of retreat.

In the course of the battle MacMahon was seriously wounded, whereupon confusion ensued as to the right of Gen. A. A. Ducrot or Gen. E. F. de Wimpffen to assume command. The German gunfire broke up the ground and inflicted enormous losses on the French cavalry under Gen. J. A. Margueritte who was killed in the fight. In the afternoon of Sept. 1 the Germans launched their main attack from east and west. The emperor Napoleon III realized that the position was then hopeless and surrendered together with nearly 82,000 officers and men.

Grave miscalculation of German strength led to the total collapse of French military power. At Sedan 17,000 French were killed or wounded. German losses were less than 9,000. Meanwhile, the other French army surrendered Metz and in Paris a provisional government of national defense was formed to face the imminent German siege. (*See* also Franco-German War.)

Battle of Sedan, 1940.—The battle of May 13, 1940, inaugurated the German invasion of France in World War II. Between the two world wars France had built the Maginot line along its eastern frontier. But the area around Sedan and the Belgian frontier was left poorly defended. In 1939 the 1st army group, under Gen. G. H. G. Billotte, was placed along the eastern line in accordance with the French Plan D, which assumed that the Germans would attack through Belgium and the northern section of the frontier. The French 2nd army under Gen. Charles Huntziger held the stretch from Longwy to Sedan.

The German high command, having learned of this plan, decided, however, to strike at three points along a 50-mi. line between Dinant and Sedan, the main blow falling on Sedan. Armoured divisions, under Gen. Paul von Kleist, reached the Belgian Ardennes through Luxembourg on May 10, pushing back the old-fashioned French cavalry. The German advance continued past Bouillon and by the evening of May 12, Gen. Heinz Guderian's 1st panzer division had reached the outskirts of Sedan.

On May 13, under cover of dive bomber attack, the Germans effected crossings north and south of Sedan. By evening the breakthrough was complete and Sedan was destroyed. Huntziger held out south of Sedan, but meanwhile Guderian had routed Gen. André Corap's forces to the west and the two other German thrusts at Houx and Monthermé farther north had succeeded. The rest of Plan D became unworkable. In June, the Franco-German armistice was signed. *See* also World War II: *The Western Front, First Phase.*

SEDBERGH, a small, ancient market town of the West Riding of Yorkshire, Eng., close to the Westmorland border, is 11 mi. (18 km.) E of Kendal in the basin formed by the junction of Dentdale and Garsdale with Lunedale. It lies under high fells within the Yorkshire Dales National Park and gives its Norse name to a rural district of three parishes and a deanery. Formerly an important stage on the roads through the Pennines, it is now popular for its majestic scenery. The local interests are agriculture, grazing, and cheese making. Sedbergh School, founded in 1525 by a native, Roger Lupton, canon of Windsor and provost of Eton, was disendowed under the Chantries Act, 1548, and refounded in 1552. Its constitution was revised in 1874 and the buildings greatly extended. (C. K. C. A.)

SEDDON, RICHARD JOHN (1845–1906), New Zealand statesman, Liberal prime minister from 1893 to 1906, was born at Eccleston, Lancashire, on June 22, 1845, the son of a schoolmaster. Brought up in the engineering trade, he emigrated to Australia in 1863, spent a short luckless period on the Bendigo goldfields, then joined the railway workshops at Williamstown near Melbourne. Early in 1866 he went to New Zealand, was moderately successful at goldmining on the west coast, and put the money he made into storekeeping. At the same time he became prominent and popular in local politics. Standing as a radical, he was elected to Parliament in 1879. He was a member continuously for west coast constituencies till his death. Verbose and tedious as a speaker, Seddon's energy and mastery of procedure made him notable, nevertheless, and when the Liberals, led by John Ballance, came into power in December 1890, he was given the important portfolio of mines and public works. When Ballance died (April 1893) Seddon was determined to have the succession, and got it; and forthwith began the masterful process that firmly established his power in the country. Powerful in body and voice, forceful, tireless, shrewd in his appreciation of men, a good administrator and a consummate politician, astute without being subtle, unable to tolerate equals around him, able not merely to jump on a bandwagon but to make the bandwagon his, with a rough geniality that went straight to the heart of the electorate, it was little wonder that long before his death he was known as "King Dick." Under his leadership the Liberal Party put through the great mass of social legislation that made New Zealand for a time an object of interest all over the world, though the measures were generally originated by others, such as William Pember Reeves (acts concerning industrial matters), John McKenzie (land), or William Hall-Jones (old-age pensions). In the imperial sphere, at home or abroad, Seddon was active and outspoken, and under him the Cook Islands were annexed to New Zealand (1901). After a last great electoral victory (December 1905) he died suddenly at sea on June 10, 1906, while returning to New Zealand from a visit to Sydney.

See R. M. Burdon, *King Dick* (1955). (J. C. Be.)

SEDERHOLM, JAKOB JOHANNES (1863–1934), Finnish geologist and an authority on Precambrian time, was born in Helsinki on July 20, 1863. He was educated at Helsinki, Stockholm, and Heidelberg. He was appointed geologist at the Geological Commission of Finland in 1888, was promoted to director in 1893 and retained this position until his retirement in 1933.

Sederholm made two major contributions: First, he vigorously promoted and directed the commission which produced numerous first-rate maps, reports, and scientific treatises. Second, he pioneered the investigation of the Precambrian rocks of Finland, studying especially the origin of granites and gneisses, and the stratigraphy, time classification and correlation of the rocks. He traveled in Europe, North America, and Asia and published many papers. He died at Helsinki on June 26, 1934. (Er. An.)

SEDGE, a grasslike plant of the family Cyperaceae (*q.v.*), especially any of the large genus *Carex*, which contains perennial species of temperate and subarctic zones, frequently growing in damp, boggy, marshy, or stream habitats.

SEDGWICK, ADAM (1785–1873), English geologist who introduced the terms Cambrian system and Devonian system (*qq.v.*), was born on March 22, 1785, at Dent vicarage, Yorkshire. He was educated at the grammar schools of Dent and Sedbergh, and at Trinity College, Cambridge, where in 1810 he was elected a fellow. In 1818 he was ordained and succeeded John Hailstone as professor of geology. He was elected president of the Geological Society in 1829–30, and in 1831 he commenced fieldwork in North Wales. This led to Sedgwick's application of the name Cambrian to the oldest group of fossiliferous strata. With Sir Roderick Impey Murchison he made a special study of the folded and faulted sandstones and shales of Devonshire known as the Culm Measures, showing that they belong to the age of the true Coal Measures (Carboniferous). Sedgwick and Murchison also introduced the geological term Devonian. These researches were published in the great memoir "On the Physical Structure of Devonshire," *Trans. Geol. Soc.* series 2, vol. 5 (1839). (*See* also ORDOVICIAN SYSTEM.) Among other works *A Synopsis of the Classification of the British Palaeozoic Rocks* (1855) may be mentioned. Sedgwick died at Cambridge on Jan. 27, 1873. The Sedgwick Museum at Cambridge (opened 1903) was built as a memorial to him.

See J. W. Clark and T. McKenny Hughes, *Life and Letters* (1890). (C. E. T.)

SEDGWICK, ADAM (1854–1913), English zoologist, best known for his researches on the wormlike *Peripatus*, was born at Norwich on Sept. 28, 1854. A grand-nephew of the geologist Adam Sedgwick (*q.v.*), he entered Trinity college, Cambridge, in 1874, there becoming attracted to zoology. He was one of the group of students inspired by Francis Maitland Balfour, leader of scientific research in comparative anatomy and embryology. In 1878 Sedgwick became Balfour's lecturer and in 1882, when Balfour was killed in the Alps, took charge of his young school of morphologists. Sedgwick's greatest researches were concerned with that remarkable animal *Peripatus* (*see* ONYCHOPHORA), an ancient link between the segmented worms and the insects. Later work confirmed Sedgwick's brilliant demonstration that the development of this animal holds the key to the relationships of several major divisions of the animal kingdom. From 1897 to 1909 Sedgwick devoted himself to his outstanding *Text-Book of Zoology*, and its publication marked the close of the great era of evolutionary morphology which began after 1859. In 1907 he succeeded Alfred Newton as professor of zoology at Cambridge, and two years later became professor of zoology in the new Imperial College of Science and Technology at South Kensington, London. He died in London on Feb. 27, 1913, after a long-standing pulmonary ailment. (C. F. A. P.)

SEDIMENTARY ROCKS. Although the term rock is commonly understood to be something durable and unyielding, and is so understood even in engineering circles, in geology it denotes only a body of solid materials forming a significant part of the crust of the earth. Included here are the unconsolidated clays and sands as well as the truly consolidated, or lithified, materials. Unconsolidated sediments, however, are not just soil. Soil is a somewhat ambiguous term and is usually applied to the very thin surficial materials, generally unconsolidated or only weakly indurated, as opposed to the bedrock upon which these materials rest and from which, in many cases, they were derived. Soil may be considered as one variety of sedimentary rock—and indeed has been called the mantle rock (saprolith or saprolite if it was produced by weathering *in situ* of the bedrock).

The sedimentary deposits form an important class of rocks. They are defined as those rocks formed by sedimentation—a process of deposition of mineral matter from (fluid) suspension or from solution at the relatively low temperatures and pressures which prevail at or near the surface of the earth. The systematic study of the properties and origins of these materials is the science of sedimentology.

This article deals with the history of sedimentology and its applications in exploration for gas and oil, the volume, origin and classification of the sedimentary rocks and the process of sedimentation. In addition to the cross references given under the various headings of this article, for explanation of the geological terms and concepts referred to *see* GEOLOGY; MINERALOGY. Modes and locations of occurrences and distinctive characteristics of various accumulations of sedimentary rocks are dealt with

in separate articles on geologic systems and epochs, as CAMBRIAN SYSTEM; PLEISTOCENE EPOCH; etc. *See* also *Geology* sections and sections dealing with physiographic regions of articles on countries and states, as CANADA; CONNECTICUT; etc.

SEDIMENTOLOGY

Petrology is concerned with the properties, classification and origin of rocks. Sedimentary petrology is that branch of petrology which deals with rocks of sedimentary origin. Some investigators have applied the term sedimentation to the body of knowledge, both observational and theoretical, concerned with the origin of sediments and sedimentary deposits (and their lithified equivalents). As the term, in the strict sense, only applies to a process, other workers have rejected it and used the term sedimentology for the science of sediments. As so used, it is more or less equivalent to the term sedimentary petrology but has tended to replace both sedimentation and sedimentary petrology.

History of Sedimentology.—Primitive man knew and made use of many sedimentary materials: flints for his spears, clay for his pottery. He soon learned where to look for these things and as his technology evolved he made many observations on and applied terms to these materials of sedimentary origin. Many of these terms derived from the common language remain and have been more precisely defined and incorporated into scientific nomenclature. Others have become obsolete and discarded. Such terms as cobble, sand, flint and limestone are among those retained; terms like hornstone or pudding stone are no longer used.

Geology had its real beginnings as a science in the early part of the 19th century. A significant event in its development was the publication in 1815 of the geological map of England by William Smith, a self-taught land surveyor and engineer. Smith's map embodied the first real attempt to portray the distribution and relative ages of the sedimentary strata of a region. Smith's contribution was in the establishment of the stratigraphic order and the discovery of the usefulness of fossils in stratigraphic correlation. The first scientific work on sedimentary rocks was essentially stratigraphic—namely the distribution of the sedimentary rocks in space and time. Field studies were directed, therefore, toward determining the order of superposition and the gross geometry of the sedimentary bodies—their thickness and lateral extent.

The science of sedimentology thus had its beginning in the science of stratigraphy to which it is closely related (*see* also STRATIFICATION). The central problem in stratigraphy is the establishment of the temporal order of deposition; the central problem in sedimentology is to determine the origin of the deposit. The early stratigraphers, however, made many observations on the character of the sedimentary strata with which they were concerned. The collective knowledge thus obtained became embodied in many scientific papers and reports. Such works as A. W. Grabau's *Principles of Stratigraphy*, published in 1913, contains an extended summary of such knowledge.

The justly famous "Challenger" expeditions of 1872–76 did much to put the study of the oceans on a scientific basis—did in fact establish the science of oceanography. The data collected by this expedition which appeared in 1880–95 in the monographic *"Challenger" Reports* by Sir John Murray and A. F. Renard shed much light on marine geology and especially on marine sedimentation. The impetus which this work gave to the study of modern marine sediments has continued. The influence of the *"Challenger" Reports* on speculations concerning the origin of the ancient sediments cannot be overestimated.

The science of sedimentary petrology or sedimentology can be considered to have been established as a separate geological discipline with the publications of two papers by Henry Clifton Sorby. Sorby's paper on the structure and origin of limestones which was delivered as a presidential address before the Geological Society of London in 1879 is a paper of such importance and merit that it can still be read with profit. A second paper "On the Structure and Origin of the Non-calcareous Stratified Rocks" which appeared in the *Proceedings* of the Geological Society of London the following year is a companion study of equal rank. Sorby can justly be called the father of sedimentary petrology. The last paper published by him, in 1908 at the age of 82, "On the Application of Quantitative Methods to the Study of the Structures and History of Rocks" foreshadowed work which was to come several decades later.

Sorby is best known for his early use, perhaps the first use, of the polarizing or "petrographic" microscope for the study of rocks and minerals in thin sections (*see* PETROLOGY: *Methods of Investigation*). This method of study, now routine for petrographers, was applied by Sorby to both minerals and rocks, especially the sedimentary rocks. But it remained for Lucien Cayeux (1864–1944), the French petrographer, to carry the microscopic study of the sedimentary rocks forward to maturity. Cayeux's monographs on the sedimentary rocks of France, especially those on the siliceous and the calcareous rocks, have never been excelled. Likewise his earlier studies of the ironstones and phosphates of France are without peers.

The study of sediments and sedimentary rocks entered a new era with the publication, in 1919, of "A Field and Laboratory Study of Cobble Abrasion," by C. K. Wentworth. This study, a master's thesis submitted at the University of Iowa, inaugurated an era of quantitative studies and laboratory experimentation. Except perhaps for the early work of Gabriel Auguste Daubrée (*q.v.*), the great French experimenter, sedimentary geology was largely an observational field science. Even the laboratory studies of Cayeux and others were primarily observational and nonexperimental. Wentworth's contribution was to formulate operational definitions for specific properties of clastic materials (*i.e.*, rocks made up of fragments of pre-existing rocks), such as roundness of cobbles, and devise methods whereby these properties could be measured. It became possible, then, to study the effects of abrasion in laboratory mills or "tumbling barrels" as well as to make a quantitative analysis of the action of streams and waves in the field. Wentworth's original paper was followed by similar quantitative field and laboratory studies by him and others. As a consequence of the collection of numerous measurements, the need for statistical summarization of these data became acute.

Although Wentworth himself attempted to utilize statistical methods, the first generally successful use of statistics in sedimentology seems to have been that of Parker D. Trask who in 1930 devised simple statistical parameters to characterize grain-size distributions in clastic sediments. The making of grain-size analyses of sediments—another quantitative procedure—had been done, however, as early as 1899 by J. A. Udden of Augustana college, Rock Island, Ill.

The study of sediments and sedimentary rocks was greatly accelerated by the establishment of a National Research Council Committee on Sedimentation in 1920. Under the chairmanship of W. H. Twenhofel of the University of Wisconsin, this committee prepared the well-known *Treatise on Sedimentation*, published in 1926, revised and republished in 1932.

Exploration for Oil and Gas.—Much of the interest in the sedimentary rocks and the accelerated development of sedimentology as a science has arisen because of the close relations between sedimentation and the formation of oil and gas. To promote the use of microfossils and heavy minerals in stratigraphy and the exploration for oil and gas (*see* also FORAMINIFERA: *Role in Petroleum Geology;* PETROLEUM), the Society of Economic Palaeontologists and Mineralogists was established in 1927. This society founded the *Journal of Sedimentary Petrology* in 1931, and this journal has been a popular outlet for researches on sediments and sedimentary petrology since that date.

Although oil and gas are caught in natural traps—mainly structural—it has been shown that their occurrence within a sedimentary basin can be better understood from studies of the distribution, both in space and time, of the various sedimentary lithologies (systems of rock) within the basin. Such studies are promoted by the preparation of lithofacies maps using data obtained both from outcrops and subsurface borings—large numbers of which have been made in exploration for gas and oil. The data so obtained, such as the number of sand beds, net sand thickness, and sand-shale ratio, can be plotted and contoured. Facies mapping of this type had to wait until adequate subsurface data from borings were avail-

able; as a result interest in the subject did not develop until after World War II.

The facies symposium, sponsored by the Geological Society of America, the proceedings of which were published as a *Memoir* of the society in 1949, did much to stimulate interest in the quantitative study of facies.

In 1938 Hans Cloos, of Bonn university, Ger., and his students began mapping of the primary sedimentary structures—cross-bedding, ripple marks, oriented fossils and the like—which record the direction of current flow during the deposition of the Devonian strata of the Rhine valley. Similar studies of cross-bedded sandstones in Arizona and in England were in progress at about the same time. Such paleocurrent studies combined with facies studies have proved not only important in the search for petroleum, but also are an aid to paleogeographic reconstruction—location of axis and trend of the ancient sedimentary basins, location of margins of basins and probable sources of the sedimentary fill, location and trend of the shore lines, etc.

The mapping of facies and directional properties of sediments has led to fusion of field and laboratory studies of sedimentary rocks and to a new phase in the development of sedimentology. This development has been furthered greatly by the study of the sedimentary framework—location and orientation of sand bodies—in modern sedimentary basins, most notably the delta of the Mississippi and adjacent gulf coastal areas.

International interest in sedimentology culminated in the calling of the first International Congress of Sedimentology in 1946 in Belgium. With the appearance of the *Treatise on Sedimentation*, various other reference and textbooks (see *Bibliography*), the establishment of a separate journal and a sponsoring society, and an international congress, sedimentology has come of age as a geological subscience.

The volume of research, represented by published papers, theses and courses taught in the universities, has grown very rapidly since the early 1930s.

THE SEDIMENTARY ROCKS

Because of the fossils entombed in them, the sedimentary rocks contain the whole of the life-record of the past. And by means of their fossil content they can be arranged in a chronological order. Moreover they also carry the record of past climate and past geography and, therefore, are of the greatest importance in unravelling the geologic and life history of our planet.

In addition, 85% to 90% of the mineral wealth of the world is derived from the sedimentary deposits or rocks. They are the reservoirs for petroleum, natural gas, and ground water. Indeed the oil and gas are as much a product of sedimentary processes as are the rocks in which they are found.

Coal is likewise a sedimentary rock and, together with petroleum and natural gas, supplies most of the energy for the industrial machine as well as raw materials for the chemical industries. Even the ores of many metals are of sedimentary origin. The principal ores of iron, aluminum, manganese and magnesium and some copper ores are of such origin. The alluvial deposits are, of course, sedimentary and many ores of tin, gold and platinum as well as gemstones occur as alluvial deposits. Most nonmetallic materials, such as building stone, the mineral fertilizers, the raw materials of the ceramic and cement industries, and rock salt, are of sedimentary origin. Clearly an understanding of these deposits, their discovery and their exploitation is basically a problem in sedimentary geology.

Volume.—The total volume of sediments, both ancient and modern, is very large. The thickness of sedimentary rocks varies greatly; locally accumulations in excess of 60,000 ft. are known. The average thickness on the continents, however, is much less and has been estimated to be about 7,000 ft. The thickness of the sediments over the floor of the ocean is highly uncertain and probably quite variable. The total volume of the sedimentary materials has not been measured and can only be estimated from geochemical calculations. If the sodium in the sea is derived from weathering of igneous rocks, at least 50,000,000 cu.mi. of average igneous rocks would be needed to furnish the quantity of sodium now contained in the oceans. But the volume of sediment released during this weathering, owing to porosity and to volume increases due to hydration and oxidation, would be somewhat greater. Inasmuch as not all the sodium released has been stored in the oceans, the total volume of igneous rock weathered (and hence the total volume of sediment produced) has been estimated to be in excess of 85,000,000 cu.mi. Some estimates, based on other considerations, suggest that the volume of sedimentary materials may be even greater. Even so, the sedimentary rocks form only a relatively small part of the outermost ten-mile shell of the earth. Of this shell, commonly called the "crust" of the earth, only 5% is of sedimentary origin.

Although there are many kinds of sedimentary rocks, some 99% can be classed as some type of sandstone, shale or limestone. Estimates based on measurement of exposed sedimentary sequences assign from 44% to 56% of the total to shale; from 14% to 37% to sandstone and the remaining 19% to 29% to limestone. The proportions of average shale, sandstone and limestone required to make the average igneous rock (from which they are presumed to have been derived by weathering) are computed to be 70%–82% shale, 12%–16% sandstone and 5%–14% limestone. The discrepancies between the observed and computed proportions are believed to be due to loss of the finest materials (which would form shale) to the deep oceanic basins.

Origin and Classifications.—Close examination of many sedimentary rocks shows that they consist of a detrital framework fraction that can only be debris derived from pre-existing rocks. This framework consists of close-packed, worn and rounded detrital elements: pebbles or cobbles of various rocks in the case of the gravels and conglomerates, and sand grains, most commonly single mineral grains of quartz or feldspar, in the case of the sands and sandstones (*see* CONGLOMERATE; SANDSTONE).

Some such deposits consist exclusively of one kind of detritus; others contain detrital material of diverse kinds. The lithified rocks, such as sandstone and conglomerate, contain a mineral cement which fills or partly fills the voids or interstices in the framework. This cementing mineral matter must be introduced therefore, after the deposition of the detrital elements and be the cause of the lithification of the rock as a whole. Commonly cementing materials are silica (quartz) and calcium carbonate (calcite). The total volume of cement may be as much as one-third or more of the whole rock.

The sedimentary materials described above are clearly the waste products of the disintegration of earlier rocks. They have been called the clastic (=broken) sedimentary rocks in recognition of the fragmental character of their detrital elements. The origin of these materials is not difficult to surmise. Remove the cement from a sandstone and one obtains a sand identical in all details with that found in streams or on beaches. The stream sands are clearly seen to form by erosion of the weathered residues of various older or pre-existing rocks. They are, however, washed residues markedly sorted and thus enriched in quartz and impoverished in the clay materials.

Other sedimentary rocks are not so formed. Some consist of a more or less cemented accumulation of shell or other skeletal debris and form a veritable fossil "hash." Such rocks must have originated from the accumulation of the skeletal hard parts of invertebrate organisms, either *in situ* or by current transport without introduction or addition of other mineral matter. Such accumulations can be found today in the coral reef areas and elsewhere. As these materials are mainly calcium carbonate, their accumulation leads to the formation of limestones and related rocks (*see* LIMESTONE; CHALK). The cliffs of the English channel are cut in thick and extensive deposits of chalk of Cretaceous age. The skeletal materials of which the chalk is composed are mainly of microscopic dimensions similar in character to those forming the calcareous muds found today in some places on the sea floor. Siliceous skeletal debris, though less common, may also form extensive and thick deposits (*see* DIATOMACEOUS EARTH).

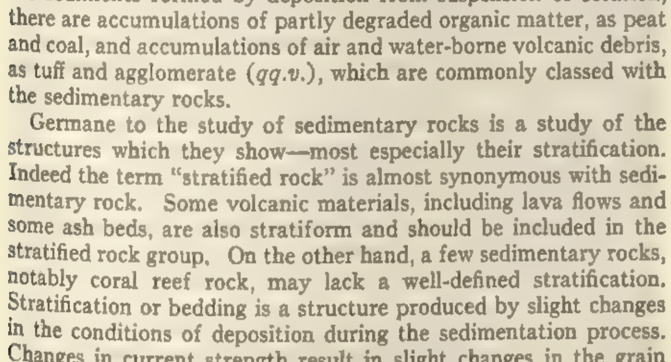
The shales appear to be the finest waste products of weathering and erosion. Under the microscope they are seen to consist of a mixture of silt particles and clay materials. The silt, like sand,

is the unaltered residue of weathering or abrasion; the clay is mainly the product of the decomposition of the feldspars of the parent rocks from which the detritus came. Not uncommonly to this silt-clay mixture is added skeletal and other biochemically precipitated carbonate and silica as well as organic materials. The hybrid sediment thus produced, upon compaction, becomes mudstone or shale (*q.v.*).

The sedimentary rocks are, therefore, accumulated sediments. Their constituents are of varied nature and their composition depends on the relative proportions of the materials of the diverse origins (*see* figure). Those consisting mainly of the products of abrasion ("rock flour") and the washed residues of weathering (sand, silt and clay) are the clastic sediments. Those consisting mainly of the biochemically or chemically precipitated materials (calcium carbonate and silica) are nonclastic sediments. Not uncommonly the sediment has a multiple origin and is in truth a hybrid deposit. Very commonly also the original composition is modified by reaction with materials in solution in the medium from which it was deposited or with those in solution in the ground waters with which it may later come in contact. The postdepositional alterations which result from such reactions with dissolved materials may lead to cementation of the sediment or drastic modification of its composition (as in the conversion of limestone to dolomite). The postdepositional changes are collectively considered diagenetic changes (*see* DIAGENESIS). Other products of diagenesis include concretions, stylolites, nodules and petrefactions.

A few rare sediments appear to be precipitated wholly from solutions. Thus formed are the extensive evaporitic sediments—the products of an evaporating brine (*see* GYPSUM; SALT: *Rock Salt*). Other sediments appear to be precipitated by reactions in more dilute solutions, as phosphorite (*q.v.*) and chert. In addition to the sediments formed by deposition from suspension or solution, there are accumulations of partly degraded organic matter, as peat and coal, and accumulations of air and water-borne volcanic debris, as tuff and agglomerate (*qq.v.*), which are commonly classed with the sedimentary rocks.

Germane to the study of sedimentary rocks is a study of the structures which they show—most especially their stratification. Indeed the term "stratified rock" is almost synonymous with sedimentary rock. Some volcanic materials, including lava flows and some ash beds, are also stratiform and should be included in the stratified rock group. On the other hand, a few sedimentary rocks, notably coral reef rock, may lack a well-defined stratification. Stratification or bedding is a structure produced by slight changes in the conditions of deposition during the sedimentation process. Changes in current strength result in slight changes in the grain sizes transported and deposited; changes in the chemical or physical environment may result in slight to marked changes in composition in the sediments forming by precipitation. Depending on the relation between the frequency of these changes and the rate of sedimentation, the stratification planes or surfaces of discontinuity may be close together or widely spaced. Sediments accordingly exhibit thin bedding or thick bedding. If the changes responsible for bedding planes are seasonally induced, the strata are then annual layers or varves (*see* VARVE ANALYSIS).



FROM F. J. PETTIJOHN, "SEDIMENTARY ROCKS"; REPRODUCED BY PERMISSION OF HARPER & BROS.

Though there are minor exceptions, the planes of stratification are initially horizontal, or substantially so. The sedimentary rocks in many places, notably in the mountain tracts, are no longer horizontal but are tilted at various angles, or even vertical or overturned (*see* FOLD). The recognition of these deformed stratified rocks as the ancient equivalents of sediments now being deposited in horizontal position, is one of the major achievements of geology for it leads to the conclusion that vast elevation and deformation of the earth's crust has taken place.

Stratification is not to be confused with rock cleavage which is a structure that commonly transects or cuts the true bedding and is a structure, therefore, that is postdepositional in origin. Another structure, also commonly confused with bedding is colour-banding—a phenomenon most characteristic of sandstones—which consists of rhythmically spaced precipitation surfaces of reddish iron oxide. These bands commonly, but not everywhere, transect the bedding.

SEDIMENTATION

Although the term sedimentation has been used as a synonym for sedimentary petrology and sedimentology, it is more properly a process. It is the process of deposition of a solid material from a fluid—usually air or water—from a state of suspension or solution. Broadly defined it would also include deposits from glacial ice and those materials collected by gravity alone—as in talus deposits, or accumulations of rock debris at the base of cliffs.

The physics of the most common sedimentation process—the settling of solid particles from fluid media—has long been known. The settling velocity equation formulated in 1851 by G. G. Stokes, is the classic starting point for any discussion of the sedimentation process. Stokes showed that the terminal settling velocity of spheres in a fluid was directly proportional to the difference in densities of fluid and solid, the radius of the spheres involved, and the force of gravity and inversely proportional to the viscosity of the fluid. Stokes' equation is valid, however, only for spheres of very small size (under 0.04 mm. in diameter) and hence various modifications of Stokes' law have been proposed for nonspherical particles and particles of larger size.

No settling velocity equation, no matter how valid, provides a sufficient explanation of even the basic physical properties of natural sediments. The grain size of the clastic elements and their sorting, the shape and roundness of these elements and their fabric and packing are the results of complex processes related not only to the density and viscosity of the fluid medium but also to the velocity of the forward motion of the depositing fluid and to the turbulence resulting from this motion and the roughness of the beds over which it moves, to various mechanical properties of the solid materials propelled, to the time or duration of the transport action and to other little-understood factors. Present knowledge, most of it empirically obtained, is inadequate to account for the known facts.

Chemical sedimentation is understood in terms of chemical principles and laws. Although the famous physical chemist, J. H. van't Hoff, applied the principles of phase equilibria to the problem of crystallizing brines and the origin of salt deposits as early as 1905, only a little effort was made to apply physical chemistry to the problems of chemical sedimentation. More recently, however, there has been investigation of the role of the redox (mutual reduction and oxidation) potential and pH (acidity/alkalinity) in the precipitation of many chemical sediments, renewed effort to apply known thermodynamic principles to the origin of anhydrite and gypsum deposits, the chemistry of dolomite formation, the problem of the ironstones and related sediments. New developments in isotope chemistry and nuclear physics are reflected in sedimentology in direct age determination of the potash-bearing minerals, notably glauconite, by the potassium-argon method, and in paleotemperatures or the determination of temperature of formation of the carbonate skeletal materials of marine invertebrates.

The geochemist also considers the sedimentation process in terms of the chemical end-results. To him sedimentation is like a gigantic chemical analysis in which the primary constituents of the silicate crust of the earth are separated from one another in a man-

ner similar to that achieved in the course of a quantitative analysis of rock material in the laboratory. The results of this chemical fractionation are not always perfect, for nature uses poor methods, but by and large the results are remarkably good. The greatest concentrations of many elements found in nature are those of the sedimentary rocks. No igneous or metamorphic process can match the sedimentation process in effective isolation and concentration of these and other elements. Geochemical differentiation or fractionation, which began in Precambrian times, perhaps 3,000,000,000 years ago, has resulted in an enormous accumulation of sodium in the sea, calcium and magnesium in limestone and dolomite, silicon in the bedded cherts and orthoquartzitic sandstones, carbon in the carbonates and carbonaceous deposits, sulfur in the bedded sulfate, iron in the ironstones, etc.

Sedimentation is most generally considered by the geologist in terms of the textures, structures, and fossil-content of the deposits laid down in different geographic and geomorphic environments. Great efforts have been made to differentiate between continental, littoral and marine deposits of the geologic record. The further classification of environments and the criteria for their recognition is still a subject of lively interest.

The analysis of the record of ancient basins of sedimentation has been promoted by the study of present-day basins. Oceanographic and limnologic expeditions have shed much light on the sedimentation in such basins as the Gulf of Mexico, the Black sea, the Baltic sea, various estuaries, lakes and fluvial basins.

SEDLEY, SIR CHARLES (1639–1701), English poet, dramatist, wit, and courtier, was baptized at St. Clement Danes Church, London, on March 5, 1639. He was the second son of a Kentish baronet, Sir John Sedley, and his wife Elizabeth, daughter of Sir Henry Savile, the great Elizabethan scholar. Admitted to Wadham College, Oxford, on March 22, 1656, he left without taking a degree. He inherited the baronetcy on the death of his elder brother in April 1656. After the Restoration he was a prominent member of the group of court wits called "the merry gang." Charles II delighted in his conversation and declared that "Nature had given him a patent to be Apollo's Viceroy." In June 1663 he took part in a wild frolic at the Cock Tavern in Bow Street, Covent Garden, for which he was fined 2,000 marks by the Court of the King's Bench. Dryden and Shadwell were among his friends and Dryden introduced him into his *Essay of Dramatic Poesy* under the name of Lisideius. His original comedy *The Mulberry Garden* was staged by the King's Company at Drury Lane Theatre in May 1668. In March 1677 his rhymed tragedy *Antony and Cleopatra* was produced at the Duke's Theatre and in May 1687 his second comedy *Bellamira or the Mistress* was acted with great success by the King's Company.

Sedley married Katherine Savage, daughter of Earl Rivers, in 1657. She became insane and was sent to a convent at Ghent probably about 1670. In 1672 he went through a form of marriage with Ann Ayscough, the daughter of a Yorkshire gentleman, and he seems to have lived with her for the rest of his life. Katherine Sedley, his daughter by Katherine Savage, though no beauty, was clever and witty. She became the mistress of James, duke of York (later James II), by whom she was created countess of Dorchester in 1686. Her father was an active supporter of William and Mary at the time of the 1688 revolution, when he is said to have remarked "Well I am even in point of civility with King James, for as he made my daughter a Countess, so I have helped to make his daughter a Queen." By Ann Ayscough he had a son who took the name of Charles Sedley and was knighted by William III. In the latter part of his life Sedley seems to have been transformed from a Restoration wit into an Augustan gentleman. He sat in all the parliaments of William III as member for New Romney and his speeches were thoughtful and sensible. He died at Hampstead in Aug. 1701.

Sedley's best play is undoubtedly *Bellamira,* a racy, amusing rehandling of the theme of the *Eunuchus* of Terence in terms of Restoration life. *The Grumbler,* his adaptation from the French *Le Grondeur* of D. A. de Brueys and J. Palaprat, is also a sparkling and lively performance. His literary reputation, however, rests on his lyrics and verse translations. His best lyrics such as the well-known "Phillis is my only Joy" have an exquisite grace and charm, while the poem beginning with the following stanza expresses deep feeling with a success only equalled among contemporary poets by his friend Rochester:

> Not *Celia* that I juster am
> Or better than the rest,
> For I would change each Hour like them
> Were not my Heart at rest.

His versions of the eighth ode of Book ii of Horace and the 4th *Georgic* of Virgil have been highly and deservedly praised.

A number of Sedley's best lyrics appeared in Hobart Kemp's *A Collection of Poems* (1672). The first collected edition of his works was published in 1702.

See V. de S. Pinto, *The Poetical and Dramatic Works of Sir Charles Sedley,* 2 vol. (1928) and *Sir Charles Sedley, a Study in the Life and Literature of the Restoration* (1927), where an account of early editions may also be found. (V. DE S. P.)

SEDUCTION, a term generally used in the special sense of wrongfully inducing a previously chaste woman to consent to sexual intercourse. A seduction action at common law stands in an anomalous position. The woman seduced has no right of action because of her consent. The action is instead given to her parent, the relationship to be protected, however, being that of master and servant rather than that of parent and child; a parent, as such, has no right of action, but must show his status as master or employer and that the seduction has deprived him of his child's services. The "loss of services" requirement is merely technical; any services actually rendered, however trifling, will suffice, and a minor daughter residing at home with her parent is without proof presumed to render such services. Furthermore, it is everywhere agreed that once a technical loss of services has been established, the parent may recover damages for medical and other expenses resulting from his daughter's pregnancy, for the loss of her society, and for his own outraged feelings. Punitive damages may likewise generally be recovered. Some states of the United States have abolished the "loss of services" requirement completely.

By the mid-20th century, the common-law seduction action in the United States had undergone significant statutory change. Thus statutes in a number of states authorize the seduced woman to sue in her own name, abolishing the common-law defense of consent. Such statutes, furthermore, have been interpreted by some courts as allowing adult married women to recover for their own seduction—a particularly unfortunate result, since the seduced plaintiff's husband likewise has a criminal conversation action against the seducer. Other courts deny relief to all women who have once been married, even though they are validly divorced when seduced. The theory of these cases is twofold: that the statutes are designed to protect virginity and not the Judeo-Christian concept of chastity, and that a previously married woman is simply too experienced to permit herself to be seduced in the statutorily required sense.

Criminal statutory-rape statutes in almost all jurisdictions have similarly been interpreted to give the seduced girl a cause of action in her own name, though only, of course, to those girls under the statutory age of consent, commonly fixed at 16 years. At the other extreme, several states, reacting to the blackmail possibilities of the seduction action and recognizing the questionable social policy involved in paying young women to abandon their virtue, have abolished the action altogether.

Seduction is not as a rule a criminal offense in England, but in the United States statutes in most states impose criminal liability upon the seducing male. The elements of the crime vary, consisting in one or more of the following: intercourse with a female

by trickery or under a promise of marriage; a requirement that the female be previously chaste; a requirement that the female be under a certain age, ranging from 18 to 25; and a requirement that the defendant be over a certain age. A seduction prosecution is barred in most states by marriage with the seducer and in others by an offer of marriage. Several states refuse to allow a conviction for seduction merely on the uncorroborated testimony of the seduced female. (D. W. Br.)

SEDULIUS SCOTTUS, poet and scholar, belonged to a group of Irish savants at Liège, where he can be traced from *c.* 848 to 860 (or 874?). His poems, mostly in classical Latin metres, include panegyrics on the emperor Lothair II, on Charles the Bald, and especially on his protector, Bishop Hartgar of Liège. A master of versification, Sedulius did not lack the human touch. His ingenious elegy on the death of Hartgar's ram blends mock-heroic elements with genuine affection and culminates in the bold comparison of the "martyred" ram with the Lamb of God. Some of his verse foreshadows the goliard songs of later times. More abstract poetry, alternating with prose, is found in his treatise *De rectoribus Christianis* ("On Christian Rulers"), one of the earliest among medieval "mirrors for princes." His commentary on the Pauline Epistles makes use of the commentary by Pelagius. As a scholar Sedulius cultivated grammatical, classical, and biblical studies. Connected with his circle are the Leiden and St. Gall copies of Priscian, with Old Irish glosses, and the miscellaneous Codex Bernensis 363, of the late 9th century, which ranks high among early manuscripts of Horace. Sedulius took considerable interest in the Greek text of the Bible. Four Greco-Latin biblical manuscripts are attributed to his circle; one of them was possibly written by his hand.

Bibliography.—His poems are edited by L. Traube, *Monumenta Germaniae historica. Poetae aevi Carolini,* vol. iii, pp. 151–240 (1896); other works in J. P. Migne, *Patrologia Latina,* vol. ciii (1851); *De rectoribus Christianis,* ed. by S. Hellmann, *Sedulius Scottus* (1906). *See* also J. F. Kenney, *Sources for the Early History of Ireland,* pp. 553–569, with bibliography (1929). (L. Br.)

SEDUM, a genus of the stonecrop family (Crassulaceae), mostly perennial herbs with succulent leaves. There are about 300 species, natives chiefly of the north temperate and frigid regions. The white, yellow, or red, rarely pink or blue, flowers are usually small and grouped in terminal clusters. They have a calyx of five sepals, as many petals, usually ten stamens and five distinct carpels, which have as many glands at their base and ripen into as many dry seedpods. More than 30 species are native to North America, widely distributed across the continent. In addition, some Old World species have become widely naturalized in the eastern states and Canada. Several species are found in Britain, including some with tuberous roots and large leaves like the orpine or live-forever (*S. telephium*), and others of smaller size, chiefly found on rocks, walls, and dry banks; *S. acre* is the wall pepper or golden moss, well known also in gardens, a variety of which, *aureum,* is in cultivation with golden-yellow tips to the leaves and shoots. Many species are cultivated for the beauty of their foliage or flowers, and many are remarkable for their vitality. They succeed on rockwork, old walls, or in garden borders; some, *e.g., S. lydium,* a native of Ásia Minor, are excellent for carpet bedding. *S. spectabile,* up to 2 ft. in height, with pink flowers in large heads, is fine for borders.

SEECKT, HANS VON (1866–1936), the officer who remodeled the German Army as the *Reichswehr* after World War I. He was born at Schleswig on April 22, 1866, and began his military career in 1885 as an ensign in an infantry regiment. After a period at the Military Academy he joined the general staff in 1899 and was sent to the Danzig Army Corps. By 1913 he was chief of staff to the Brandenburg Army Corps with the rank of lieutenant colonel. Throughout World War I Seeckt served on the staff. In February 1915 he was promoted colonel and became chief of staff to the 11th Army under Gen. August von Mackensen. In this capacity he played a leading part in the successes of the Central Powers against the Russians at Gorlice-Tarnów in May 1915 and in the subsequent invasions of Serbia (1915) and of Rumania (1916–17). After serving as chief of staff of the Turkish Army in the field from December 1917, he returned to Germany in November 1918 and took command of the *Grenzschutz Nord,* in East Prussia. His war service had not been spectacular, but he had won the reputation of being an exceptionally able staff officer who, unlike many of his contemporaries, always had an eye to the political aspect of a military problem.

It was after World War I that Seeckt rendered his most notable service. By the military clauses of the Treaty of Versailles, the German Army was limited to 100,000 men and, to prevent the creation of a reserve, service was to be for 25 years for officers and 12 for noncommissioned ranks. The Great General Staff was abolished, and the Germans were forbidden to have any aircraft, tanks, or heavy artillery. It fell to Seeckt to fashion to the best advantage the small, lightly equipped force that Germany was allowed to maintain as the *Reichswehr.* The extent of his success was seen in the speed with which this force was expanded after 1933 when Hitler came to power and the military clauses of the Versailles Treaty were disregarded. Seeckt created an army that was in fact the nucleus of a force of 35 divisions; and its leaders, trained to assume at short notice much higher ranks and responsibilities than those they actually held, were instructed by theoretical means to handle the modern equipment they were forbidden to possess.

In November 1919, Seeckt became chief of the *Truppenamt* or Troops Bureau, the organ whose relation to the new Ministry for the *Reichswehr* was equivalent to that of the former Great General Staff to the old War Ministry. On June 15, 1920, three months after the failure of the *Putsch* led by Wolfgang Kapp and Gen. Walther von Lüttwitz, he was appointed chief of the army command (*Heeresleitung*) in succession to Walther Reinhardt. The *Putsch* had produced disturbances, some of them Communist-inspired; and there had been clashes between the *Freikorps* (independent volunteer bands) and *Reichswehr* units. It was in these unpropitious circumstances that Seeckt began to remodel the *Reichswehr.* He had two principles in mind: to make it the kernel of a future national army, and to make a substantial part of it into the core of a mobile shock force. Instinctively distrusting mass armies, and convinced that in any future war trench warfare must be avoided at all costs, he probably regarded the second of his principles as the more important. In this remodeled army men such as Fedor von Bock, Gerd von Rundstedt, Albert Kesselring, and Heinz Guderian, who were to lead the German armies in their early successes in World War II, served as comparatively junior officers.

In the years immediately following his appointment Seeckt showed acumen in emerging on the right side in any political crisis or disorder, including Adolf Hitler's unsuccessful *Putsch* of November 1923. His policy was always to maintain the power and prestige of the *Reichswehr* by avoiding internal dissension and open conflict with Germany's former enemies. He supported a mild liaison with the Red Army, but discouraged internal left-wing activities, because they clashed too violently with the imperial tradition. In military matters his policy was to circumvent the more irritating restrictions imposed by the Treaty of Versailles, without arousing the Allies' suspicions. His measures included the setting-up of armament factories in the U.S.S.R., the training of German tank crews and air pilots in the U.S.S.R., and the training of "temporary volunteers" in the *Reichswehr.*

In 1926 Seeckt, who had many enemies, made two blunders: he issued an order regularizing dueling among officers; and he approved an application by Prince William of Prussia (son of the former crown prince) to take part in training with the 9th Infantry Regiment. As a result of these indiscretions, and the political pressure of his opponents, he was dismissed by President von Hindenburg on Oct. 8, 1926. Thereafter he spent much of his time in political activities, serving as a conservative member of the *Reichstag* in 1930–32. In 1934–35 he was sent on a mission to China to advise Chiang Kai-shek on the reorganization of his army. He died suddenly of a heart attack in Berlin on Dec. 27, 1936.

Seeckt's *Gedanken eines Soldaten* appeared in 1929 (Eng. trans. *Thoughts of a Soldier,* 1930). In 1933 he published *Deutschland zwischen West und Ost,* in which he declared himself against the notion of a Reich extending "from Lake Peipus to Calais," but

recommended the destruction of Poland and union of Germany with Austria. His memoirs, edited by Gen. F. von Rabenau, were published posthumously in two volumes, *Aus meinem Leben* (1938) and *Aus seinem Leben* (1940).

SEED, a new generation in the life of a plant. Typically the ripe seed consists of a partially developed young plant (the embryo) provided with an abundant food supply (endosperm) and enclosed in a protective seed coat. In size seeds range from the dustlike seeds of begonia and orchid to the large nutlike seeds of the double coconut palm or Coco de Mer (*q.v.*), the fruit of which often reaches a foot in length and 40 lb. in weight. The mature seed usually is air dry and in a resting condition. In nature the seed is important as a means of carrying plant life over periods unfavourable for growth and as a means for distributing the plant in space and in time. In agriculture the seed is important in two ways: (1) the food stored in the seed for the development of the new plant can also serve as an important food source for man and animals (wheat, beans); (2) with most annual crop plants the seed is the start of the new crop each year. To a great extent the yield and quality of the crop depend on the quality of the seed planted. The quality of the seed depends on both its genetic background and its ability to germinate and to produce strong plants.

BIOLOGY

Development.—The seed develops from an ovule in the ovary of the flower (*q.v.*). The male germ nucleus from the tube of the germinated pollen grain unites with the egg cell within the ovule. This fertilized egg divides and develops into the embryo, which is the beginning of a new plant. The stage of development of the embryo at seed maturity varies from the well-formed plantlet of pea or corn to the slightly developed embryo of an orchid, a small spherical mass of cells in which the beginnings of embryo plant parts, cotyledons, hypocotyl and epicotyl (*see* below), are barely distinguishable. As the embryo develops, the other parts of the ovule also grow and develop until the seed is mature. The integuments of the ovule, which are a part of the mother plant, develop into one or more layers to form the seed coat, or testa. Details of the development of the seed from the ovule are found in articles on Gymnosperms and Angiosperms.

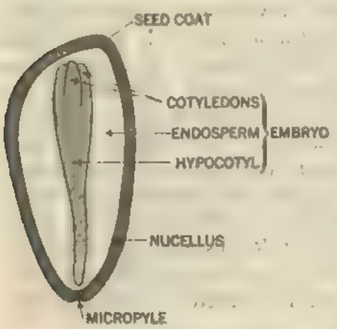

FIG. 1.—LONGITUDINAL SECTION OF PINE SEED

Structure.—The structure of seeds may be described first in general terms, although the details for different types of plants differ greatly. The embryo has one or more cotyledons (seed leaves) below which is the hypocotyl, with the growing point of the root at its tip, and above which is the epicotyl, with a growing point for new stem tissue. The embryo is surrounded by the endosperm with its food reserves or occasionally by the perisperm developed from the nucellus of the ovule. In the seeds of some plants, *e.g.*, the pea family, Leguminosae, the food reserves of the endosperm are absorbed to form enlarged cotyledons. The endosperm is enclosed by a seed covering (largely the seed coat). In some seeds thin layers remaining from the nucellus or the endosperm may form an important part of the seed covering. The details of seed structure differ in gymnosperms and in angiosperms. In gymnosperms the embryo with two to many cotyledons is buried in the endosperm. In pine seeds 6 to 15 needlelike whorled cotyledons, the number varying with the species, surround the small epicotyl. The cotyledons and epicotyl are attached at the top of the cylindrical hypocotyl. The endosperm is enclosed by the comparatively thick and tough seed coat.

In angiosperms the embryo may have one cotyledon (monocot) or two (dicot). Corn is fairly typical of many monocot seeds. The well-developed embryo is at one side of the seed. The hypocotyl and root tip are enclosed by a thin sheath (coleorhiza) and the epicotyl, with two or three young leaves formed, is enclosed in its sheath (coleoptile). The large shield-shaped scutellum almost encloses the axis, and one surface is in contact with the starchy endosperm. The scutellum is attached to the axis between the hypocotyl and the epicotyl, and is considered by many to be a special development of the single cotyledon. A thin seed coat and the adhering fruit coat surround the embryo and the endosperm.

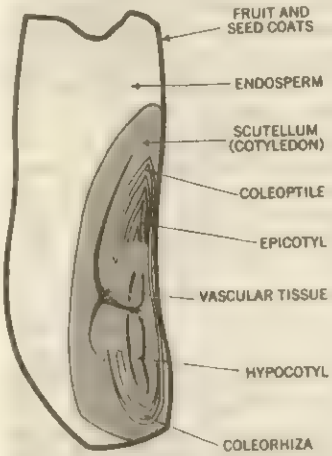

FIG. 2.—LONGITUDINAL SECTION OF GRAIN OF CORN, A MONOCOT SEED

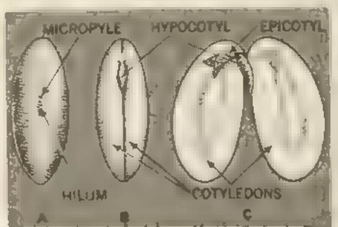
The castor bean is representative of a dicot seed with much food stored in the endosperm. The embryo with two thin, broad cotyledons enclosing the small epicotyl and the short cylindrical hypocotyl are embedded in the endosperm. The whole is covered by the hard, brittle seed coat. In the bean, typical of many dicots, a well-developed endosperm of the immature seed is gradually absorbed by the enlarging cotyledons until at maturity only a thin membranous layer remains. At maturity the large food-filled cotyledons protect an axis consisting of a cylindrical hypocotyl and an epicotyl with two or three leaves already evident. This large embryo is enclosed by a comparatively thin covering of combined testa and endosperm.

The developing seed, attached to the placenta of the ovary by the funiculus, receives food through its vascular strand. At maturity the seed separates from the funiculus, leaving a scar called the hilum. The shape and position of the hilum often are a distinguishing character useful in the identification of seed kinds. The micropyle is a small porelike opening in the ovule, where the ovule coverings, or integuments, meet and the pollen tube usually enters. In some seeds the micropyle is visible when the seed is mature, but usually it is closed by cuticle or wax. In the bean it can be seen near the hilum. The raphe is seen as a slight ridge along one side of some seeds. The raphe is the result of the fusion of the funiculus to one side of the ovule (bean and pansy). The area at the end of the vascular tissue of the funiculus is known as the chalaza. Sometimes a rough outgrowth called a caruncle develops near the hilum (castor bean). The additional or partial covering outside the seed coat that develops on some seeds (water lily) after fertilization is called an aril.

The outer surfaces (epidermis) of some kinds of seeds may have characteristic modifications. Cotton fibres are formed as extensions of some of the epidermal cells of the seed coat. In contrast, a smooth cuticle forms on the epidermis of the lima bean seed and makes the surface hard and shiny.

The seeds of flax have thickenings of the epidermal cell walls that swell in water and become gelatinous. In turnip, cabbage and related seeds, a network of ridges, formed as a result of differences in heights of epidermal cells, gives the seeds a characteristic pitted appearance.



FROM EDMUND W. SINNOTT, "BOTANY: PRINCIPLES AND PROBLEMS," REPRODUCED BY PERMISSION OF MCGRAW-HILL BOOK COMPANY

FIG. 3.—BEAN, A TYPICAL DICOT SEED

(A) Face view of seed; (B) face view of the embryo after the seed coat has been removed; (C) the two cotyledons spread apart

The general form of different kinds of seeds is in part determined by the orientation of the ovule with respect to the placenta on which it is borne. Four types of orientation have been described. The orthotropous, or atropous, ovule is straight and erect, with the micropyle in line with the funiculus. The anatropous ovule is completely inverted, with the funiculus fused along one side so that the micropyle is close to the hilum. The campylotropous ovule is curved,

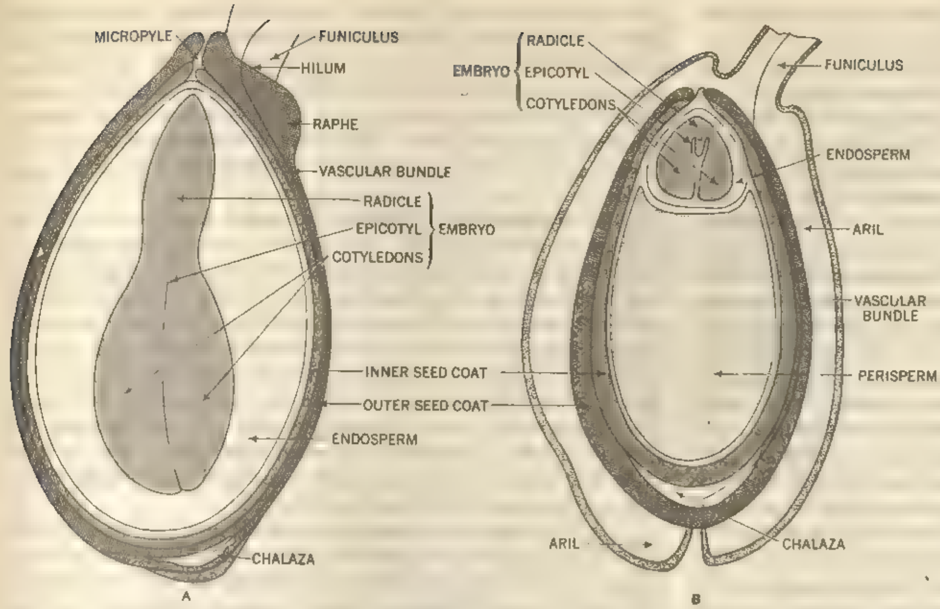


FIG. 4.—VERTICAL SECTIONS THROUGH TWO SEEDS: (A) PANSY; (B) WATER LILY

bringing the micropyle near the chalaza. The ovule is called hemitropous when it is half inverted but straight and has the hilum on the side of the ovule.

Composition.—The compositions of different kinds of seeds show great variation. The cotyledons of soybeans and peanut have a high oil content, but in bean the oil is replaced by starch. The seeds of all legumes have a high protein content. In cereals (corn, wheat, etc.) the embryos are high in oil and protein, but the endosperm, which occupies the greater portion of the seed, is high in starch. The oil of the castor bean seed is in the cells of the endosperm. A few seeds, *e.g.*, onion, contain sugar as a reserve food. The immature seeds of sweet corn and garden pea contain much sugar, but most of it changes to dextrin or starch by maturity. Layers of hemicellulose are deposited as thickenings of the cell walls of the endosperm of carrot, date and other seeds, and serve as food reserve.

Adaptations for Distribution.—The seed represents an inactive state in the life history of the plant and thus is itself an adaptation for distribution in space. It is relatively insensitive to changes of surroundings and lends itself admirably to transportation from place to place by wind, water, and animals. It was for this reason also that the seed made possible the development of agriculture by primitive man—the seed could be kept from one crop season to the next and could be carried from one region to another. As man selected plants for food, the seeds of many crop plants tended to lose their natural ability for survival in the wild and became largely dependent on man for preservation from season to season.

Special structures of seeds and fruits, adapting them for wide distribution, have developed during the evolution of plants. These adaptations vary greatly in nature, as do the means used for distribution.

Wind Distribution.—Wind is an important factor in seed distribution. The very small size of many seeds may be considered as an adaptation that allows them to be borne long distances in the air. Small grass seeds have been collected by airplanes at elevations from 200 to 3,000 ft.

The dandelion bears many one-seeded fruits to which are attached tufts of fine hairs that act as parachutes or sails. The seeds of the milkweed, when they burst out of their pods, have similar hairs that aid the wind in carrying them abroad. The cattail head has countless closely packed, tiny seedlike fruits, each with fine hairs attached; when the fully ripe head is disturbed, the expansion of the closely packed hairlike attachments pushes the seeds out into the wind to be carried away.

The much heavier seeds, or seed-bearing fruits, of pine, maple and ash trees have large, flat wings that permit the seeds to glide a moderate distance from the mother tree.

Among some plants the adaptation for distribution by wind is found in the form and structure of the entire plant rather than in the form of the seed or fruit. Several species of plants, belonging to different families but all known as tumbleweeds, are bushy and when mature nearly spherical. The main stem at the soil surface is weak and breaks readily. As the wind rolls these detached plants across fields and plains, the seeds gradually are loosened and fall to the soil. The Russian thistle and the tumbling mustard are common examples.

Many wild plants shed some of their seeds in winter after snow has fallen, and these may be blown considerable distances on the frozen surface of the snow.

Water Distribution.—Water is another natural agent for the dissemination of seeds and fruits. Aside from resistance to germination with the first absorption of water, the principal adaptation for water distribution is low specific gravity, permitting many seeds and fruits to float for long periods. One of the most noteworthy examples is the fruit of the coconut, which has a fibrous outer coat with many air spaces and a smooth outer surface. Shortly after a new island had been formed in the Pacific ocean by a submarine volcano in the Krakatoa group of islands, many germinating coconuts were found on the volcanic sand of the beach; some had sent down roots and become established plants. In addition to the coconuts, seedlings of several other tropical plants were found, all having developed from seeds washed up on this barren beach from distant islands. The seeds had floated long distances undamaged by sea water because of their protective coatings.

Animal Distribution.—Animals and birds are other agents for seed dispersal. After a walk in the fields in autumn, a person may find many seeds and burrs attached to his clothing. These burrs cling equally well to the fur of passing animals. Different species of plants have evolved various special forms for attachment, but all depend on projections with recurved hooks at the tip or with tiny reversed teeth. The devil's-pitchforks, the flattened fruit of a plant of the sunflower family, has two long prongs with many reverse pointing barbs. The sticktight is the pod of a plant of the pea family that has tiny spines with hooked tips; the pods are jointed and easily break apart into one-seeded segments. The cocklebur is a two-seeded burr with comparatively long hooked spines.

Fleshy fruits and berries may be considered as special adaptations of the plant that serve to aid in the distribution of seeds by animals and birds. The seeds of most fleshy fruits have tough coverings that resist digestion. The seeds remain in the excrement, ready to grow when they are deposited in some new location. The fruit of the mistletoe has a sticky covering, so that the seeds stick to the beaks of birds, to be scraped off later on the bark of a tree.

Distribution by Expulsion.—Some fruits have special adaptations that violently expel the seeds to distances of several feet from the mother plant. The pansy and the violet have three-parted pods that split into three boat-shaped segments. As the ripe pod dries, the sides of each segment close together and violently expel the seeds, one at a time. The two halves of the pod of the vetch and of other legumes split apart, and then each half twists and curls, thus violently throwing the seeds for some distance. The seeds of the touch-me-not or impatience are borne in a pod that develops strong differences of tension. When the fruit is ripe these tensions are so great that the least touch will cause

the pod to split apart; the segments curl violently and expel the seeds to a distance of several feet.

Adaptations for Preservation.—Seeds may be adapted not only for distribution in space but also for preservation of their viability over unfavourable conditions, thus providing distribution in time. When mature, the seeds of many plants, especially weeds and native species, are dormant and require special conditions before they will germinate. Some seeds, notably those of the pea family, have seed coats impervious to water (hard seeds). This impervious coat must be weakened by bacterial action in the soil, by mechanical scarification (scratching the seed coat) or by other treatment before the seeds can absorb water and germinate.

The seeds of many winter annual weeds (*e.g.*, chickweed, shepherd's purse and upland cress) that ripen in late spring or summer do not germinate while the weather is still warm, but they start to grow with cool fall temperatures. Other seeds germinate only after the moist seeds are exposed to light. As long as they remain buried in the soil the seeds are dormant, but when they are brought to the surface and receive light they germinate. It has been found that this response to light is controlled by a reversible photoreaction that also controls stem elongation, leaf expansion, flowering and other plant responses (*see* PHOTOPERIODISM). Germination of light-sensitive seeds is promoted by red light and prevented by radiation near the limit of visibility (far red). The seeds of many temperate zone plants have deep-seated and prolonged dormancy. The embryos must undergo chemical and growth changes (afterripening) before germination is possible. Most such seeds (many trees and shrubs) afterripen when held moist and cool for varying periods. In nature, afterripening occurs as the seeds lie in moist ground for one or more winters. It may be accomplished artificially by holding the seeds in moist sand or other media at temperatures a little above freezing for one to several months, the period depending on the species. (*See* PLANT PROPAGATION.)

Longevity.—The longevity of seeds of different kinds of plants varies greatly. Hard impervious coats protect the embryos so that they may persist for many years. Seeds of legumes taken from herbarium specimens known to be more than 100 years old have germinated. A very striking example of long life is shown by the seeds of the oriental lotus (*Nelumbo nucifera*); these were recovered from an ancient peat bog in Manchuria and germinated and produced flowering plants. Radiocarbon dating of seeds from

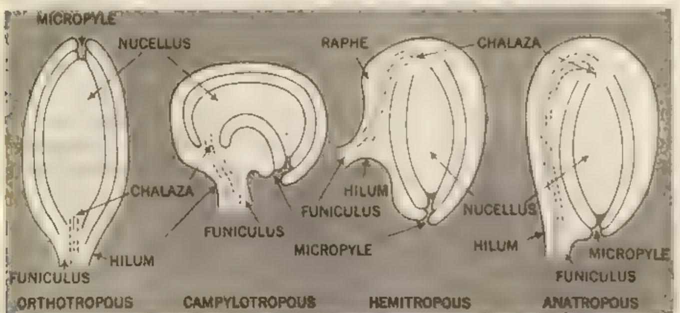

FIG. 5.—TYPES OF OVULES

the same source indicated an age of approximately 1,000 years. In contrast to this, the seeds of willow and poplar remain viable only a few weeks. The seeds of many plants, especially weeds, may remain viable for many years when buried in the soil. In an experiment in which seeds of 107 species were buried in the soil so as to permit recovery, those of 51 kinds grew after 20 years and those of 36 after 39 years. Seeds of both crop plants and weeds were included. The longevity of field and garden seeds depends on the moisture content of the seeds and on the temperature at which they are held. Low moisture and low temperature ensure long life. (E. H. T.)

AGRICULTURE

SEED TRADE

Factors affecting the production of satisfactory food crops include seed, soil type, fertilizers, cultural methods, weather, and control of insects and diseases. Unless seed true to name and of high quality is sown, the crop may be a commercial failure even though all other factors are at an optimum level. For greatest success not only should the seed be of high quality and true to name, but it should also have high vitality and be free of disease organisms and weed seeds. To ensure that the demand for high-quality seeds is met is the constant concern and duty of the seed trade.

Early Beginnings.—Man has grown and saved seed ever since he began cultivating plants. Seed growing as an industry, however, was hardly recognized as such until the early 18th century. The first commercial production of seed occurred in northern European countries, but this was followed within the same century by similar production in North America. The Shakers in New York state developed a business of growing and distributing to home gardeners over a dozen different kinds of vegetable and herb seeds. In the early 19th century some acreage of garden pea seed was grown in Ontario for the D. Landreth company, a U.S. firm. By 1847 this same company had 250 ac. of pea seed in Pennsylvania. Seed acreages increased steadily after that.

Prior to actual seed production in the United States, a number of seed dealers, of whom David Landreth was the first (in 1784), became established, principally in Philadelphia, but also in New York and Boston. These merchants imported seeds from European producers, and, until World War I, Europe continued to be the chief source of vegetable seed for most of the world. With the advent of that war, and again as a result of the dire need for seed in World War II, commercial seed production in the United States was greatly increased, as was seed production in Australia and New Zealand.

Climate and Seed Production.—During the 20th century, climate has become more of a determining factor in the location of areas where seed is grown than earlier in the history of the seed trade. This has been especially true within the United States, where there has been, and still is, a definite movement toward greater seed production in the western states. Low precipitation supplemented by adequate supplies of irrigation water has made it possible to produce vigorous crops free from disease. During the period of seed maturity and harvest, dry air and absence of rain facilitate the collection of high-quality seed. In Europe some northern seedsmen arrange for certain crops to be grown in countries to the south, where ideal conditions for seed production exist.

Various areas of the world have become associated with the production of certain seed crops. Among the producers of field seeds, Canada is known for the production of alfalfa, various clovers and grasses. Many of these same crops, except alfalfa, are grown in Denmark in sufficient quantity for export. France has long been a big producer of various field seeds; so also has Italy. All the field seeds are grown in large quantities in the United States, and, in spite of the movement in production to the western part of the country, over one third of the principal field seeds were produced in the north central states in the 1950s. Before World War II Czechoslovakia, Rumania and Poland supplied large quantities of these seeds, and Hungary was noted for production of clovers.

Such vegetables as cabbage and related crops, as well as spinach and beets, thrive best under conditions of high humidity in areas adjacent to the sea; hence they are widely cultivated for seed in the northern European countries such as the Netherlands, Denmark and England, as well as around the Puget sound area of the Pacific northwest in the United States. Japan also produces such types of seed extensively. In both Europe and Japan, curing of the seed often presents difficulties because of inclement weather. In such regions the moisture content of seed sometimes has to be reduced by artificial drying even after it has been cleaned.

In southern France and Italy, as well as in parts of adjacent countries, such vegetable seeds as lettuce, endive, onion and carrot, which require dry atmospheric conditions prior to and during harvest, are widely grown. Similar crops, and in addition peas, beans and sweet corn, are grown in the western United States except in the Pacific northwest. California, with a wide range of climatic conditions, grows a greater variety of such seeds than any other state, but they are also widely cultivated in Idaho and

the eastern sections of Oregon and Washington and to varying degrees in other western states. Some seed crops such as tomatoes, peppers, eggplants and watermelons, and to a lesser extent the other vine crops, are often grown for seed in the same regions where they are cultivated for processing and marketing. While tropical countries are not normally considered as a source of seed for temperate climates, there is some evidence that such seed can often be successfully grown if the crop is planted at the correct time at a high elevation where temperate climatic conditions exist.

Many of the flower seeds are grown in the Netherlands, France, England and the United States, particularly California, and to a lesser extent in the Pacific northwest and some eastern states.

Size of Industry.—The seed industry has considerable economic value aside from its importance as a source of seed for other varied businesses. Seedsmen, or at least seed dealers, are located in practically every country of the world. In those countries where seed is grown on a commercial scale, there are large capital investments in office buildings, warehouses, seed and many types of farm and specialized machinery necessary for the handling of seed crops, as well as trucks, other vehicles and the innumerable items associated with a highly diverse type of business. Figures on actual acreages and production are not available for the seed industry as a whole. Statistics collected by the agricultural marketing service of the U.S. department of agriculture give an idea, however, of the extent of production in that country. In general total seed acreage remains fairly constant from year to year, although acreage of individual kinds of crops may fluctuate greatly. Field seeds (alfalfa, grasses, clovers, etc.) excluding small grains were harvested from well over 3,000,000 ac. every year during the 1960s. At the same time 170,000 to over 200,000 ac. were devoted annually to the production of vegetable seeds. Of this latter acreage approximately 95% was occupied by the large-seeded vegetables—beans, peas and sweet corn—and 5% by more than 35 small-seeded vegetables. In contrast to the large acreages devoted to farm and vegetable seeds, there are about 6,000 to 7,000 ac. of flower seeds in the United States. Seed acreages in Europe, while differing as regards specific crops and varying from year to year like those in any seed producing area, are in general of the same over-all magnitude.

Types of Activity.—Seed production is a rather complex business enterprise in which the actual growing of seed is only one of many activities. Comparatively few seed companies are involved in seed-growing operations. Most of them as jobbers or retailers handle seed as a commodity rather than as a product that they produce. Many producers are also wholesalers and as such often operate large organizations among whose employees are plant breeders, production supervisors and fieldmen, warehouse men, seed analysts and salesmen. Often among warehouse employees are men especially trained to operate the numerous seed cleaning machines. Jobbers aid in the distribution of seed through their buying and selling operations. Retailers are most numerous in the trade. Most of them operate small stores, the business of which is not limited to seed. Some large producers retail their products by mail through seed catalogues. In such catalogues field seeds may be merely listed as to name and price, but the varieties of vegetables and flowers are often illustrated and described in detail. Still other producers market their seed by means of commission packets placed in grocery and other types of stores.

Growing the Seed.—In general two types of seed are produced and handled by all seed growers—stock seed and market seed. Stock, foundation or "mother" seed is seed grown and used by seedsmen to produce market seed. Market seed is the product that is sold. Stock seed must be of the highest quality, and in particular it must be absolutely pure as regards variety. It is the seedsman's most prized possession, for on it much of his reputation as a seedsman rests, and without good stock seed no producer can long stay in business and make a profit.

In growing the seed, and particularly stock seed, the best cultural practices must be employed and care must be taken to ensure adequate isolation from growing crops of a similar kind in order to prevent cross-pollination with related plants. Plants of the same species found growing along the margin of the field are cut down before they develop flowers and endanger the purity of the seed crop by cross-fertilization. Weeds particularly should be kept to a minimum in seed crops. They not only compete with the crop for moisture and nutrients, but their seeds become mixed with those of the crop and later can be separated only with difficulty. During the growing season, especially when the seed crop is approaching the flowering stage, all plants that show characteristics dissimilar to those of the particular variety under cultivation are carefully removed—a process known as roguing. With root and bulb crops that have to be dug and replanted after the root or the bulb has matured, off-type plants are usually rogued at that time. Severe roguing is more essential in a crop of stock seed than it is in market seed. The latter often needs no roguing if grown from strictly selected stock seed. Harvesting at the proper stage of maturity calls for great care and experience. If the seed is harvested too early, yields and quality may be reduced by immature seed; if harvested too late, seed may be lost by shattering or shedding. Methods of harvesting, curing and threshing vary according to the kind of seed produced, as well as the country or section in which it is grown. Machinery is commonly used wherever possible in harvesting and threshing operations. However, some of the flower seeds are grown on such a small scale that even if a machine could be used it would hardly be feasible. Where machines are used, they have to be thoroughly cleaned of seed between each crop. Although production and handling procedures are fundamentally alike for all seeds, those followed with field seeds do differ in some respects from those required for vegetable and flower seeds.

Field Seeds.—Trade in field seeds flows in general in two directions, particularly within the United States. This comes about largely because in certain regions the production of field seeds was a regular part of the cropping system prior to the period when specialty growers were becoming more common. The farmer producing clover or grass seed commonly sells to a local jobber or elevator man, who is either an agent of some wholesaler or is in touch with the general market. Such lots are shipped to a large dealer by whom the seed is cleaned, graded, bulked and bagged in accordance with quality and designated by the various grade names used by the dealer. Sales are then made to country merchants who, in turn, sell to the farmer. In some seed-producing sections, especially those far removed from terminal markets, large dealers have established plants in which field seeds are cleaned prior to shipment to a central warehouse.

Many field seeds are a world commodity. Price thus often depends on the available supplies in countries offering seed for sale. There is consequently a more or less constant movement back and forth, and a given lot of clover seed, for example, may be exported and later imported, depending on price fluctuation.

Production of Field Seeds.—Although field seeds are grown extensively by general farmers, there is a definite trend toward production by special growers. With the increasing development of new varieties and strains of alfalfa, grasses and clovers specially selected for definite regions, growers having the proper aptitude find it profitable to devote much of their farming operations to seed production. The steadily increased use of certified varieties of field seeds has done much to encourage growers to specialize in seed production. Within the United States, crop improvement associations operate in most of the states, and these organizations establish certification services in conjunction with public agencies such as experiment stations, state extension services or state departments of agriculture. Through a system of inspections and detailed records, officials are able to certify that crops grown by properly authorized farmers are true to name, free of varietal and mechanical mixtures, noxious weeds, etc. Similar certification practices have been established in Canada as well as in some European countries. An International Crop Improvement association has been in existence since 1919. Certification procedures for growing seed became necessary with the release of improved varieties from experiment stations and similar agencies. Certification tags on each bag of seed attest to the variety and quality of seed.

Verification of Origin.—Before the development of improved varieties, it was discovered through experimentation that commercial alfalfa and red clover seed grown in one country or in one section within a country were not always adapted to other areas having different soil and climatic conditions. In 1927 a seed verification service was inaugurated in the United States. This service verifies the origin of much of the domestic uncertified alfalfa, red clover and open-pollinated field corn and requires that the seed is so labeled. Imported alfalfa and red clover seed are artificially coloured to indicate country of origin. Verification of origin will continue to be a necessary service so long as the old common varieties are offered for sale.

Vegetable and Flower Seeds.—The production of vegetable and flower seeds tends to be more specialized than that of the field seeds, and control of the industry is maintained more within the trade itself. Practically all vegetable and flower seedsmen have their own stock seed of each variety that they handle. Such seed is usually grown by the seedsman on his own farm under his direct supervision. In contrast, most market seed, the volume of which normally exceeds by many times that of the stock seed, is grown under contract. Seedsmen make contracts with farmer-growers who grow the market seed from stock seed supplied by the seed company. Such a practice is common in all the large seed-producing areas of the world. Any unused stock seed, together with all the market seed produced, is the property of the seed company. The grower is paid on the basis of a certain price per pound of clean seed produced. Contract growing has come about partly because of the great diversity of vegetable and flower seed crops, and partly because many of these are grown for seed in areas other than those where they are commonly grown as a food or an ornamental. There are over 40 different kinds of vegetables and literally thousands of varieties. The number of kinds of flowers is even greater, and each of these in turn has many varieties. Much of the competition within the vegetable and flower seed industry is the development of new varieties and the maintenance of superior strains of standard ones. Certification of vegetable seeds is extremely limited and that of flower seeds practically unknown.

Many companies, almost by necessity, operate on an international scale. Northern European companies may produce their stock seed in their home country but, through branches or through contract arrangements with other companies or individuals, grow much of their market seed in a country more suited to such production. A number of U.S. firms have production stations in widely separated sections of the United States, and in addition sometimes make arrangements for market seed to be grown for them in Europe, Japan, Mexico or elsewhere. Likewise, European seedsmen have some of their supplies grown in North America.

Breeding and Selection.—With the tremendous increase in knowledge of plant genetics and modern techniques of plant breeding, the specialist in this field has become of increasing importance to progressive seed companies. Not only do such companies often wish to develop new varieties of their own, but they also need to increase new releases from experiment stations and other government agencies. Since such varieties have often been developed for resistance to such factors as diseases, insects, heat, cold and drought, they may also wish to transfer if possible such characteristics to already established varieties. Such programs require skilled plant breeders and often considerable investment on the part of the company. The increasing production of first-generation, or F_1, hybrids of corn (both field and sweet), onions, tomatoes, sorghums, petunias and other crops often necessitates elaborate breeding and production programs. *See* also PLANT BREEDING.

Processing Seeds.—Preparing seeds for market is a most important function of the wholesale dealer. All seeds as they come from the producer contain a certain proportion of dirt and weed seeds, all of which must be removed. Large dealers are equipped with cleaning mills of various kinds. Although screening and fanning mills are still the basic equipment required for seed processing, many ingenious and specialized machines for handling seeds have been developed. Equipment is available so that seeds can be separated on the basis of specific gravity, friction, adhesion, light and colour (by electric eye), as well as handled by the old standard procedures. Processing includes more than cleaning. With the increasing use of precision planting machines, seeds often need to be bulked on the basis of rather exact sizes, and this some seedsmen are prepared to do. In all plants of any size, seed is processed in line, which means that from beginning to end of the operation, the seed is mechanically transferred from one machine to the next without having to be set aside to await further handling. Such co-ordination of machinery to maintain an even flow requires skillful supervision by trained personnel. Throughout such operations a complete record of the various seeds being processed has to be maintained so that no mixtures occur. As the processing of each is completed, it is labeled as to its lot number, variety, strain, grower, etc., so that the seedsman can, if necessary at a later date, easily trace its history.

Legislation Affecting the Trade.—Many countries and most states within the United States have laws regulating the sale of seed, but these laws vary in detail. In general, such laws require the giving of certain information covering percentage of purity, of germination and of weed seeds present, place of origin and similar facts. In some states, the sale by trade of seed containing more than a specified number per unit of weight of certain noxious weed seeds, such as dodder, is prohibited. Owing to the fact that seed laws are not uniform in the various states, large dealers are compelled to attach various tags to shipments in accordance with the laws of the state to which the seed is consigned. Some weeds are considered noxious in one state or region but not necessarily so in another.

Laws in many countries regulate the importation of seeds and affect the movement of seed in international trade. Import licences are required in some countries. By such means, domestic producers are often protected. Domestic prices may be maintained at a higher level than otherwise and domestic production is encouraged. There are regulations in a number of countries to limit the sale of seed to those varieties that have been tested and approved by governmental agencies. A seedsman's problems are therefore by no means disposed of when he has grown and processed a crop of seed. He may still have the task of placing it in trade. (L. R. H.)

SEED TESTING

The scientific testing of seeds before planting, recognized as an essential aid to agriculture, is performed to determine the value of seeds for planting. Such testing reveals, for example, the proportion of seeds labeled white clover that are actually white clover seeds, the percentage of these that could produce plants, and the presence of seeds of noxious weeds.

History.—Seed testing developed first in Europe with the rapid expansion of agriculture in the second half of the 19th century. The practical application of botanical knowledge to determine the value of seeds for planting apparently developed more or less simultaneously in several countries, but leadership usually is credited to Frederick Nobbe, who established a laboratory for testing seeds in 1869 at Tharandt, Ger. Within a few years seed-testing laboratories were started in Denmark, the Netherlands and Switzerland. E. H. Jenkins, of Connecticut, while studying in Europe, was much impressed with the seed-testing work of Nobbe. Jenkins included in the 1876 report of the Connecticut Agricultural Experiment station a statement of the possible advantages of seed studies to American agriculture. Late in the 19th century botanists and agronomists at various state agricultural experiment stations tested seeds for farmers and determined the quality of those on the market. During this period, W. J. Beal of Michigan and C. E. Bessey of Nebraska were especially active in laying the foundations for seed testing in North America and interesting their students in seed studies. G. H. Hicks, a student of Beal, organized seed-testing work in the United States department of agriculture in 1896.

Governmental Controls.—The early work by several states and by the department of agriculture showed that much of the seed in commerce had low germination capacity, contained seeds of many weeds and often was adulterated with seeds of similar ap-

pearance but with low agricultural value. Much seed that had no other use than for the adulteration of other seed was imported. The generally low quality of seeds led, early in the 20th century, to the passage by several states of laws regulating the sale of seeds. These laws all were based on the premise that the farmer should have the details as to the quality of the seeds he bought. They required that all agricultural seeds be labeled as to percentage of pure seeds, inert matter, other crop seeds and weed seeds and as to the percentage of pure seeds capable of germination. Most state laws also designated the weeds especially troublesome in the respective states as "noxious weeds" and required a listing of the seeds of any such noxious weeds and a statement as to their rate of occurrence.

Each state controls the sale of seeds within its borders, just as it does the sale of other materials, but the federal government has power to control importations and interstate shipments. The first federal law concerning seeds, enacted in 1912 and administered by the United States department of agriculture, referred only to the purity and the weed-seed content of a few agricultural seeds. After several successive amendments, a new Federal Seed act, which prohibited the importation of all important agricultural and vegetable seeds unless they met certain minimum standards of purity and germination, was passed by congress in 1939. This act also required the truthful labeling as to purity and germination of agricultural and vegetable seeds entering into interstate commerce. The Federal Seed act is brought up to date by amendments from time to time. The foregoing is only a general outline of the practices of seed control and does not cover all features.

As might be expected, the seed-testing practices used in the United States followed in general those developed in continental Europe. Although the general methods of seed testing are similar, the details of the control of seed sales vary greatly in the different European countries. In Canada a system of seed grades has been developed to replace the labeling for purity, germination, and so forth. These grades represent an attempt to evaluate the different qualities of seed lots. Seed control in Canada is under the dominion government. The laboratory seed-testing procedures used in Canada, like those of the United States, are for the most part similar to those developed in Europe.

Testing Procedures.—The first step in seed testing is to be certain that the sample of seed accurately represents the lot of seed from which it is drawn. If the sample tested is not representative, the results of the test cannot accurately indicate the value of the entire lot of seed. Procedures for adequate sampling of seed lots have been worked out.

Purity.—The separation of four components of a seed lot is known as the "purity test." A representative portion of the seed sample of suitable weight is separated first into seeds and other material called "inert matter" (chaff, stems, fungus bodies, dirt, etc.). The seeds are separated into pure seeds (as labeled), seeds of other plants grown as crops, and seeds of weeds. Each portion is weighed and the percentage of each is calculated. Each kind of seed is identified and listed. Because even very small proportions of noxious weed seeds are important, a much larger sample than is used for the regular purity test is examined for the presence, the identification and the rate of occurrence of each kind of noxious weed seed found. Seeds of many kinds of weeds occur in the different crop seeds, and many of these are superficially similar to the crop seeds or to each other. The seeds of some related crop plants are very much alike and separable only by special study. Identifications are based mainly on the analyst's familiarity with the seeds but may be based on comparison with correctly identified samples or with illustrations. An analyst needs thorough knowledge of plant classification and must be familiar with the appearance of many kinds of seeds.

Seed as it comes from the harvester contains much foreign material and may carry excessive weed seeds. This seed must be processed to make it as clean as possible. Many seed companies have their own analysts who make many special tests at different stages of processing to evaluate the success of the cleaning operations. Also, successive germination tests may be made to learn the effectiveness of attempts to remove immature or injured seeds.

Viability.—The viability of seeds is determined directly by finding whether the seeds will germinate. This measurement of viability is not as simple as it may appear to be. Seeds are young plants whose growth processes have been suspended. In general these growth processes are resumed when the seeds are supplied with moisture and placed at a suitable temperature for germination. Nature, however, has developed various special provisions in certain kinds of seeds to prevent germination under conditions unfavourable for seedling development. Even in the absence of special requirements, seeds of different kinds have different moisture and temperature needs. Living seeds are subject to many hazards during harvesting, processing, storage and shipping. A seed does not lose life all at once, but certain parts may be injured or certain organs may die before others. Because the purpose of seed testing is determination of the value of seeds for planting, a seed cannot be counted as germinated unless it is able to develop into a plant capable of continued growth. A seed may show some signs of life and yet be worthless to the farmer. The evaluation of seedlings (determination of which seedlings can develop into useful plants) is an important part of the germination test and it requires much experience as well as knowledge about plant structure and normal plant development.

In order to handle many samples and to provide standard reproducible conditions, analysts carry out most viability tests under artificial but controlled conditions. They provide a suitable material to supply moisture (the substratum). This may be blotting paper, absorbent paper, moss, sand or suitable sterile soil. The substratum used varies with the kind of seed, the test conditions and the space available. Counted seeds are spaced on a suitable moist substratum and placed in a cabinet maintained at sufficiently high humidity to prevent drying of the substratum and at a temperature optimum for the particular type of seed. Many seeds, including clover and onion, must be kept cool to germinate; others, such as watermelon and cotton, must be kept warm. For good germination, seeds of bluegrass and many other plants must be kept cool at night and warm during the day. At suitable intervals, as the seeds germinate, the normal seedlings, which have all essential parts for a plant, are removed and the number recorded. Standard times for making counts of each kind of seed have been worked out.

Dormancy.—For varying periods after harvest, seeds of some species will not germinate under conditions usually favourable for germination. Such seeds are called "dormant" and must not be confused with dead seeds. The potential value of dormant seeds for planting can be determined by special procedures. For example, freshly harvested wheat will germinate if the temperature is lowered 5° to 10° C. below the usual temperature for germination, or if the seeds on the moist substratum are held at a few degrees above freezing for three to seven days. Freshly harvested bluegrass seeds and the seeds of some varieties of lettuce will germinate only after a suitable exposure to light.

Hard Seeds.—Seeds of some plants of the pea and morning-glory families have impermeable coats (the seeds do not absorb water when put on a moist substratum). These hard seeds are reported separately on the analysis label. Hard seeds usually are viable, and their viability can be checked by scratching the coat in some manner and then placing the seeds under suitable conditions for germination. The proportion of impermeable seeds of some crop plants increases with increased dryness of the surrounding air. The agricultural value of hard seeds varies greatly with the species or variety and the proposed use of the seeds.

Chemical and Other Tests.—Many attempts have been made to estimate the viability of seeds without actually germinating them. These methods depend on measuring by physical or chemical means some characteristic of a viable or of a dead seed. Because the development of a useful plant depends on many processes in many tissues of the seed, none of these quick methods has been entirely successful. The most nearly successful quick test, developed by Georg Lakon of Germany, depends on soaking the seeds in a weak solution of a salt of tetrazolium. Certain enzymes of the viable embryo reduce the colourless soluble salt to an insoluble red compound. The method has definite value for obtaining the approximate viability of seeds that require a long time to germinate,

but it does not promise to supplant the usual germination test.

Seed tests of other types are often required. With the development of many new varieties with special adaptations, it is increasingly important for a grower to know whether a seed lot is of the variety shown on the label. Usually the variety cannot be determined by examination of the seeds. Often it is necessary to plant the seeds and grow mature plants. Sometimes, however, the variety can be identified in the seedling stage, either directly from seedling appearance or from differential responses to special growing conditions such as temperature or length of day. For example, commercial seeds of annual rye grass having awns broken off cannot be separated by appearance from the awnless seeds of perennial rye grass, but they can be distinguished by a chemical property of the seedlings. The roots of young seedlings of annual rye grass growing on filter paper change the paper in contact with the roots so that it shows a blue fluorescence under an ultraviolet lamp in a dark room. Seedlings of perennial rye grass do not cause this change.

The region of origin of a seed lot can often be determined from the presence in the sample of weed seeds, incidental soil or rock particles characteristic of the region. It may be important to know the origin because seeds reproduced for many years in a given region may, by natural selection, have developed qualities that make them of little or of great value for crop production in some other region.

Some seed laboratories can determine whether seed-borne plant diseases occur in seed samples. The fungi causing the diseases are identified from spores washed from the seeds or developed on young seedlings. Sometimes distinctive symptoms develop on the seedlings.

The moisture content of seeds may be determined in connection with other seed tests. A sample for a moisture test must, of course, be submitted in a moisture-proof container. Interest in seed moisture arises from the knowledge that high moisture content is an important factor in the loss of seed viability in transit and in storage.

Statistics.—The special problems of statistics as applied to seed testing have received much attention. A knowledge of statistics and of normal distribution is important because the tests are made on a small sample of the seed lot. A second small sample will differ in composition from the first, and therefore it is important to know the amount of variation that normally may be expected. "Tolerances" have been applied in seed-law enforcement because of these expected variations of small samples.

Seed-Testing Associations and Rules.—Early in the development of seed testing it became obvious that many definitions and methods of procedure must be established and that these should be uniform in different laboratories. This need led to the organization of seed-testing associations that agreed upon rules and procedures. In 1896 a committee of the Association of American Agricultural Colleges and Experiment Stations described standard seed-testing apparatus and outlined methods of procedure for testing seeds. This information was published in 1897 as *Circular 34* of the United States department of agriculture. The formation of the Association of Official Seed Analysts of North America in 1908 assured more formal co-operation. This association, which consists of workers engaged in seed testing in the several states, the United States department of agriculture and the Canadian department of agriculture, continues to be increasingly active. The development of rules for the testing of seeds was one of the main objectives of this association. The first formal rules, adopted in 1917, have repeatedly been revised, brought up to date and published by the association. The United States department of agriculture also publishes rules and regulations as required for the enforcement of the Federal Seed act. These two sets of rules are in very close agreement.

Those doing seed testing for commercial seed companies have formed the Society of Commercial Seed Technologists. This group co-operates closely with the Association of Official Seed Analysts.

An International Congress of Seed Testing was held in Europe in 1905 and at several subsequent times. In 1924 the International Seed Testing association was organized; it continues to bring about uniformity of seed testing to facilitate international commerce in seeds. Procedures for testing seeds have been similar in the different countries, but differences in definitions and in interpretations have developed. As a result, reports from different countries on tests of the same lots of seed have not always been in agreement. The International Seed Testing association adopted international rules for seed testing at a congress in 1931, but it was not until 1953 that complete agreement was reached and truly uniform international rules were adopted.

Developments in Seed Research.—The improvement of seed testing to make it increasingly useful to agriculture has been based on seed research. Not only those engaged in testing seeds but also botanists interested in classification and plant physiologists interested in life processes have advanced knowledge about seeds.

Detailed studies of similar-appearing seed types have revealed characteristic differences of form, markings or structure by which the seeds can be distinguished. The results of such studies are the basis of illustrations, descriptions and keys used in the identification of seeds.

Other studies have shown that high seed moisture and high temperature during storage are causes of weakened seeds that eventually die. The weakened seeds produce seedlings of reduced vigour and also abnormal seedlings that cannot grow into useful plants. The difficulties of the interpretation of the results of germination tests are increased by seedlings of borderline value. It has been found that mechanical injuries to seeds during harvesting and processing often result in abnormalities and death.

The research of many workers has shown that the germination of different kinds of seeds is benefited by exposure to light during germination and also that the germination of a few kinds is prevented by exposure to light. It was found that the promotion of germination is caused by a comparatively narrow band of light in the red portion of the spectrum and that seeds promoted by this red light can be prevented from germinating by exposure to far-red light (near the limit of visibility). Whether a seed is promoted or inhibited by white light depends on the relative sensitivity of the particular kind to red or to far-red radiation.

Studies of the germination requirements of seeds of many species that are very difficult to germinate have demonstrated that many of these grow promptly after they are held on a moist substratum at a temperature just above freezing for from one to several months. Rose and apple seeds are typical examples.

Further research may reveal physical or biochemical methods of distinguishing similar-appearing kinds of seeds. The moisture and temperature conditions needed to keep seeds viable are known, but the changes within seeds that lead to weakness and death have had little study. The results of such studies would aid in developing better means of maintaining seeds at high vitality, thus reducing the amount of low-quality seed on the market. Very little is known about the changes within seeds that result in dormancy or about the internal processes that accompany the overcoming of dormancy. Further knowledge about such changes would make it possible to devise more dependable methods of determining seed viability. (E. H. T.)

SEELEY, SIR JOHN ROBERT (1834–1895), English historian, apologist of the British Empire, and author of *Ecce*

Homo, a life of Christ that proved a landmark in liberal theology. Born in London on Sept. 10, 1834, he was educated at the City of London School, and (1852–57) at Christ's College, Cambridge, at which he became a fellow and classical lecturer. In 1863 he became professor of Latin at University College, London, and in 1869, as professor of modern history, returned to Cambridge, where he died on Jan. 13, 1895.

As a historian, Seeley learned accuracy in the Ranke school, but differed from Ranke in viewing history as the servant and teacher of the statesman, with a duty to take up an attitude to contemporary issues. His most solid historical work was probably *The Life and Times of Stein* (1878), but deservedly better known are *The Expansion of England* (1883) and *The Growth of British Policy* (2 vol. 1895; with memoir by G. W. Prothero). These won wide recognition for their treatment of the burning issue of colonial expansion: Seeley's view of the role of the colonial powers as trustees inspired succeeding generations.

In *Ecce Homo* (1865; anonymous but later acknowledged) Seeley presented Christ in human terms, ignoring, but not explicitly denying, the doctrine of his divinity; and in *Natural Religion* (1882), he set out the possibility of a Christianity without the supernatural, which he saw as an excrescence. Although he protested that these omissions did not imply disbelief, his works provoked controversy.

SEFERIS, GEORGE (Gr. Giorgos) (pen name of Georgios Seferiadis) (1900–), Greek poet, essayist and diplomat, who won the Nobel prize for literature in 1963, was born on March 1, 1900, in Smyrna (Izmir), Turk. He was educated in Athens, after his family went to live there in 1914. Later he studied law in Paris. In 1926 he joined the Greek diplomatic service, and served in London and Albania before World War II, during which he was with the free Greek government. After the war he held posts in Ankara and Beirut, and was Greek ambassador in London (1957–62).

Seferis was at once acclaimed as "the poet of the future" on the publication of *Strophe* ("Turning Point," 1931), his first collection of poems. It was followed by *Sterna* ("The Cistern," 1932), *Mythistorema* ("Mythical Story," 1935), *Himerologion katastromatos 1* ("Log Book I," 1940), *Tetradio gymnasmaton* ("Exercise Book," 1940), *Poïimata* ("Poems," 1940), *Himerologion katastromatos 2* (1944), the long poem *Kichle* ("Thrush," 1942), *Poïimata 1924–1946* (1950) and *Himerologion katastromatos 3* (1945). Selections of his poetry have been translated into English, French, German, Italian, Spanish and Swedish, the fullest English version being that by Rex Warner (*Poems*, 1960), which was awarded the William Foyle prize for poetry. Seferis also translated poems by T. S. Eliot and others into Greek, and wrote essays, of which the chief are *Dokimes* ("Essays," 1944) and *Erotokritos* (1946). He received the Kostis Palamas prize for poetry from the Academy of Athens in 1947. He is the most distinguished Greek poet of "the generation of the '30s," which introduced full-scale symbolism to modern Greek literature. His refined lyricism and the freshness of his diction brought a new breath of life to Greek poetry. His work is permeated by a deep feeling for the tragic predicament of the Greeks, as indeed of modern man in general. (Ce. A. T.)

SEGANTINI, GIOVANNI (1858–1899), Italian painter, known as a painter of the Alps and hard peasant life, was born at Arco in the Trentino on June 15, 1858. His mother died when he was four and his father went to Milan, leaving Giovanni in the care of a poor relative. At the age of seven the child ran away to the mountains and was employed by peasants as a herdsman. He spent long hours of solitude in drawing. His fame became known to the local authorities, who sent him to the school of art at Milan. In 1882 he settled in Brianza near Como and four years later sought the Swiss Alps, finally settling in the Engadine among the humble shepherds and farmers. There he gave himself up to the study of mountain life, and became in truth the painter of the Alps.

The "Ave Maria" took a gold medal at the Amsterdam exhibition (1883). The atmosphere of this picture is clear and crystalline, and his figures stand out in sharp relief. "The Drinking Trough" received a gold medal in Paris (1889) and "Ploughing in the Engadine" (Munich Pinakothek) gained a gold medal at Turin (1892). Besides those works in which he studied simple effects of light and Alpine scenery, such as "Midday on the Alps" and "Winter at Savognino," he also painted symbolical subjects: "The Punishment of Luxury" and the "Unnatural Mothers." He died on Sept. 28, 1899, at Maloja, Switz., where a museum contains many of his works, including the great unfinished triptych of "The Alpine World."

SEGESTA (Gr. Egesta), an ancient city of Sicily, about 2 mi. NW of modern Calatafimi. It was the chief city of the Elymi, a people for whom a Trojan origin was claimed by Thucydides; they are archaeologically indistinguishable in the Early Iron Age (first half of the 1st millennium B.C.) from their Sicanian neighbours (*see* Sicani). Segesta became in its material culture almost a Greek city, but it generally took the Phoenician side against its Greek neighbours; boundary disputes with Selinus (*q.v.*) were frequent from 580 B.C. onward. One of the ostensible objects of the Athenian expedition to Sicily in 415 was to aid Segesta against Selinus in a dispute about boundaries and rights of intermarriage. After its failure (413), the Segestaeans turned to Carthage; when in 409 Hannibal, son of Gisgo, invaded Sicily and sacked Selinus, Segesta became a Carthaginian ally. It was besieged by Dionysius in 397. In 307 Agathocles marched on the city, massacred many of its inhabitants, sold the rest into slavery, and changed its name to Dicaeopolis; but it soon recovered its old name and returned to the Carthaginians. Early in the First Punic War, however, the inhabitants massacred the Carthaginian garrison and allied themselves with Rome; they had to stand a severe siege from the Carthaginians (260 B.C.). Segesta was treated with favour by the Romans; it was a free city and the territory of Eryx may have been assigned to it.

The theatre, perhaps of the 3rd century B.C., and an unfinished Doric temple of the late 5th century B.C. are well preserved, and there are fragmentary remains of houses and the town walls.

See R. van Compernolle, "Ségeste et l'Hellénisme," *Phoibos*, vol. v, pp. 183–228 (1950–51); for the temple, *see* A. W. Lawrence, *Greek Architecture*, pp. 180 ff. (1957). (T. A.; T. J. Dn.; X.)

SEGHERS, CHARLES JEAN (1839–1886), Belgian Roman Catholic priest, missionary, twice bishop of Vancouver Island and archbishop of Oregon City, was born at Ghent on Dec. 26, 1839. Although his parents died while he was a young boy, Charles Seghers received a good education, and his preparation for the North American missions was made at the American Seminary of Louvain. He was ordained on May 31, 1863, and soon embarked for the diocese of Vancouver Island. His labours in this diocese were interrupted by his attendance at the first Vatican council as theologian to his bishop, Modeste Demers, whom he succeeded in March 1873. The new prelate continued his missionary activity in the northwest and Alaska until his appointment as coadjutor to the archbishop of Oregon City in 1878. His several visitations in his new archdiocese took him to Idaho, Montana, northern California and throughout Oregon. When the archbishop, Francis N. Blanchet, retired, he was succeeded by his coadjutor, who received the pallium at Portland, Ore., on Aug. 15, 1881. Archbishop Seghers' immediate task was the development of the Catholic school system. In 1883 he journeyed to Rome with other U.S. archbishops to prepare the schema for the proposed Baltimore council, which he attended in 1884. While he was in Rome, the see of Vancouver Island became vacant, whereupon Seghers offered to return to his former diocese since a successor was more readily available for Oregon than the more northern diocese. He repossessed the see of Vancouver Island on April 2, 1885. During a visitation to Alaska, he was murdered by a demented companion on Nov. 28, 1886.

See Maurice de Baets, *Apostle of Alaska: Life of C. J. Seghers*, Eng. trans. by Sister Mary Mildred (1943). (F. G. McM.)

SEGHERS (Segers), **HERCULES PIETERSZ** (1589/90–*c.* 1638), Dutch painter and etcher of stark, fantastic landscapes, was born in 1589 or 1590, probably in Haarlem, and became a

pupil of Gillis van Coninxloo in Amsterdam. In 1612 Seghers entered the painters' guild in Haarlem but was back in Amsterdam by 1614. In 1631 he resided in Utrecht, and in 1632 or 1633 he moved to The Hague. Early reports indicate that he was lonely and poor, even though several artists, including Rembrandt, gave evidence of their admiration for his work. Seghers' style contrasts strongly with the main aspects of the Dutch output of that period; most of his works would have been difficult to understand prior to their rediscovery in the 20th century.

The majority of Seghers' works represent forbidding mountain scenes with jagged cliffs, desolate valleys, broken tree trunks, and scant traces of human habitation, but he also painted and etched a smaller number of serene panoramas of his native countryside which deeply influenced Dutch painters of the "national" school. His etchings belong to the most original and impressive experiments in the history of print making. He used different-coloured inks and often printed on coloured or dyed paper and even on canvas; the diversity in the appearance of each individual print was increased by his adding accents by hand. The one large collection of original etchings, in Amsterdam, indicates Seghers' colouristic daring and technical skill. One plate was later owned by Rembrandt, who reworked Seghers' figures of Tobias and the Angel into those of a *Flight into Egypt*. Seghers' paintings are rare; few are documented, and a large number of forgeries exist. His *Mountain Landscape* in the Uffizi in Florence was formerly attributed to Rembrandt who seems to have altered parts of it.

G. van Gelder in *Oud Holland* (1950, 1953); Catalogue, *Hercules Seghers Exhibition*, Museum Boymans, Rotterdam (1954). (W. Sw.)

SEGOVIA, ANDRÉS (1893–), Spanish musician acclaimed as the foremost guitarist of his time, was born at Linares, near Jaén, Andalusia, on Feb. 17, 1893. He was self-taught as a musician, and first appeared as a guitarist at Granada in 1909 and later gave concerts at Barcelona and Madrid and in South America. In 1924, he won wide praise following a concert in Paris. Under the influence of Manuel de Falla and from the desire to establish the guitar as an instrument for the performance of cultivated music, he extended its repertory to include transcriptions of lute and harpsichord works by Couperin, Rameau, J. S. Bach, and others. He also inspired works for the guitar by several modern composers including Mario Castelnuovo-Tedesco, Joaquín Turina, and Albert Roussel. His repertory was extensively recorded.

See B. Gavoty, *Andrés Segovia* (1955).

SEGOVIA, a town and province in Old Castile, Spain. Pop. (1960 mun.) 33,360. The town lies north of the Cordillera Central (Cordillera Carpetovetónica), 3,297 ft. above sea level and 87 km. (54 mi.) N.W. of Madrid by road. Founded about 700 B.C., it was an important place in Roman times. It was taken at the beginning of the 8th century by the Moors, from whom Alfonso VI recaptured it in 1079. Thereafter Segovia enjoyed prosperity and a position of some importance in medieval Castile. During the reign of the emperor Charles V the revolt of the *comuneros* (common people) caused some destruction. An outbreak of plague at the end of the 16th century ushered in a long period of decadence, but the town's fortunes began to revive with the railway-building era in the 19th century.

There are two well differentiated areas: an upper town encircled by ancient walls situated on a narrow limestone ridge between the Eresma and its tributary the Clamores; and a lower part outside the walls. The centre of the old town is the Plaza Mayor (or del Generalísimo Franco) on one side of which stands the cathedral and from which streets lead into the outer suburbs. Crossing the Plaza del Azoguejo, the focal point of the town's communications, is the Roman aqueduct known as El Puente. It is one of the finest and best preserved examples of its kind, built probably in the reign of Trajan, from dark coloured Guaderrama granite without the use of mortar. Still in use, the aqueduct consists of a double tier of arches and carries water from the Río Frío for about half a mile across the valley outside the old town. At its highest point above the ground it stands 93½ ft. high.

J. ALLAN CASH—RAPHO GUILLUMETTE

ALCÁZAR, A CASTILIAN STRONGHOLD BUILT MAINLY IN THE 14TH AND 15TH CENTURIES AND EXTENSIVELY RESTORED AFTER 1862

The 16th-century Gothic cathedral was designed by Juan and Rodrigo Gil de Hontañón to replace the church destroyed during the revolt of the *comuneros*. Construction began in 1525 and was virtually finished by 1577. There are also several other fine ecclesiastical buildings including the Romanesque churches of San Esteban (12th–13th century) with a superb tower; San Martín (12th century); la Trinidad (11th–12th century); San Lorenzo (12th century); San Millán (12th century); Vera Cruz (13th century), the former church of the Knights Templar; and San Juan de los Caballeros (11th and 12th centuries), now the Museo Zuloaga of ceramics. Across the Eresma is the Gothic Hieronymite monastery of El Parral and also outside the walls is the Dominican convent of Santa Cruz (15th century) founded by Ferdinand and Isabella and now a welfare centre. In the Carmelite convent (17th century) is the tomb of St. John of the Cross.

The Alcázar, mentioned as early as the 12th century, was the fortified palace of the kings of Castile. Most of the original palace was destroyed by fire in 1862 but has since been extensively restored. There are many houses and palaces built between the 15th and the 17th centuries. Modern buildings include the palace of justice and the offices of the civil government. Segovia has an artillery academy in the former convent of San Francisco, a provincial museum and an archaeological museum.

In the late middle ages Segovia was the centre of a flourishing textile industry. As this declined agriculture took its place. The town now has factories for rubber, pottery, flour, biscuits, artificial fertilizers, cement, chemical products, etc.

Segovia is linked by road and rail with Madrid and also with the north of Spain.

Segovia Province (area 2,683 sq.mi.; pop. [1960] 195,602), formerly part of Old Castile, is bounded north and northeast by Burgos and Soria, southeast by Guadalajara and Madrid, southwest by Ávila and northwest by Valladolid. It is primarily an agricultural tableland, 2,500 ft. above sea level, producing wheat, rye, barley, hemp, flax and vegetables, and also rearing sheep, cattle, mules and pigs. The sierras in the province are quarried for granite, marble and limestone. The province is traversed by the Madrid-La Coruña railway which passes through its capital, the only city of importance.

Segovia was the scene of heavy fighting during the first months of the Spanish civil war. (M. G. Sa.)

SEGRÈ, EMILIO GINO (1905–), U.S. physicist, cowinner of the Nobel Prize in physics for 1959 with Owen Chamberlain for discovering the antiproton, was born in Tivoli, Italy on Feb. 1, 1905. He took his doctor's degree in physics at the University of Rome in 1928. He served on the staffs of the Universities of Rome and Palermo. After 1946 he was professor of physics at the University of California at Berkeley. After 1948 he

was also at the Lawrence Radiation Laboratory of the University of California. Segrè became a U.S. citizen in 1944.

An associate of Enrico Fermi when the epoch-making discovery of slow-neutron effects was made in Rome in 1934, he discovered (1937) the first artificial element, technetium, while at Palermo, using materials irradiated in one of the Berkeley cyclotrons. At Berkeley he made the first chemical separation of nuclear isomers, changed by chemical means the radioactive decay constant of beryllium and took part in the discovery of the element astatine and of plutonium-239, of which he determined the slow-neutron fissionability. He conducted extensive researches in high energy physics, including the discovery, with Chamberlain, Clyde E. Wiegand, and Thomas Ypsilantis, of the antiproton in 1955. In the 1960s he was contributor of several articles to *Encyclopædia Britannica*.

See also ANTIMATTER.

See T. N. Levitan, *Laureates: Jewish Winners of the Nobel Prize* (1960). (E. M. Mc.)

SEGREGATION, RACIAL, the practice of restricting people to certain limited areas of residence or to separate institutions (schools, churches) and facilities (parks, playgrounds, restaurants, restrooms) on the basis of race. In the United States such restrictions developed primarily as one aspect of relations between whites and Negroes, especially in the South, although other groups, such as Chinese and Japanese, have at times been affected. But segregation and the establishment of colour bars are not confined to the relations between white and coloured populations; coloured races—Asian Mongols, African Bantus, American Aztecs—have been great conquerors throughout the ages and have practised discrimination including segregation of subject races. The most extreme system of segregation, in which occupation as well as race and religion were equally important elements, prevailed in the caste system of Hindu India (*see* CASTE [INDIAN]). The history of racialist theory and thinking and studies of racial attitudes are dealt with in the article INTERRACIAL RELATIONS. (*See* also APARTHEID and related material under ANTI-SEMITISM; CLASS, SOCIAL; GHETTO.) For the U.S. Supreme Court decision in the case of *Brown* v. *Board of Education* (1954) declaring racial segregation in public schools to be unconstitutional, *see* EDUCATION, HISTORY OF. (*See* also *Education* sections of articles on individual states.)

Segregation appears always as a means of maintaining the economic advantages and the superior social status of the politically dominant racial group. This does not lead necessarily to spatial or physical segregation because the social segregation of the subordinate group may be maintained through a system of etiquette and symbols and exclusion from intimate social contacts that would reduce the social distance between the races. In an urban industrial society it becomes more difficult to maintain the physical and spatial segregation of races, and more dependence must be placed upon institutions to maintain it. Consequently, as the result of segregation, the races live in different social worlds and communication between them is restricted no matter how close they may be physically.

Racial segregation as an ecological process should be differentiated from racial segregation which is the result of a conscious or deliberate social policy. As an ecological process racial segregation is in a sense a natural process since it results from a relatively impersonal competition between races for space or land. An example of racial segregation as an ecological process is the concentration of Negroes in the areas of the U.S. South known as the Black Belt. These areas were congenial to development of the plantation system of cotton production (*see* SOUTH, THE). Ecological segregation may also be seen in cities where in the absence of legal enactments or social pressure various racial and cultural groups, because of their economic status, have created Little Sicilies, Jewish ghettos and black belts. It should be noted, however, that racial segregation as an ecological process is not a purely biotic or symbiotic phenomenon as among subhuman living organisms. Among human beings there is always social interaction involving the influence of customs and laws and human sentiments. During the process of ecological segregation human beings seek close association with those who have the same interests or similar traditions and values. Even within the same racial and cultural communities there is ecological segregation on the basis of age, sex, education, occupation and income. Hence, the social process can never be completely separated from the ecological process except for the purpose of analysis.

As far as the economic relations of races are determined solely by competition, a racial division of labour may emerge which results in the "segregation" of racial groups in different occupations. The racial division of labour is rarely due to an impersonal competitive process but more generally reflects the distribution of power in a community. Thus, the system of Negro slavery and the economic organization of life in the U.S. South as well as in the colonial areas in Africa represented a racial division of labour, but in all these cases the relation between that division and the distribution of power is clear.

When, however, members of different races have access to the same education the racial division of labour tends to break down. If competition on an individual as opposed to a racial basis is not permitted racial conflicts arise and the politically dominant race attempts to maintain its superior status by establishing a system of racial segregation.

The distribution of power in a biracial community is not only important in determining the economic relations of races but it is of equal importance in determining their social relations or their status in the social order. In fact, race relations can only be said to exist where, as sociologist Robert E. Park has stated, "racial differences enter into the consciousness of the individuals and groups so distinguished, and by so doing determine in each case the individual's conception of himself as well as his status in the community."

The phenomenon of racial segregation has appeared in all parts of the world where there are biracial communities except where racial amalgamation has occurred on a large scale, as in Hawaii and Brazil. In Brazil, where there has never been a system of racial segregation, the dominant economic and political position of the whites was never challenged by the rise as a group of persons of Negro derivation to economic and political power. In the transformation from a feudal to a middle-class society in the 19th century the mulatto was the most mobile element in the military, economic and political sectors of Brazilian society. (*See* BRAZIL: *The People*.) On the other hand, in the southern states of the United States the emancipation of Negroes brought them into economic competition with the white working class, and during Reconstruction following the American Civil War it was the political power of the Negroes that helped to consolidate the power of northern industrial capitalism. Since the proportion of Negroes in the population of the South has decreased and their concentration in the Black Belt has declined there has been some relaxation of segregation in public relations. But the white working class continued to refuse to permit Negro workers to compete, especially in white collar occupations where status is important, and whites of all classes continued to exclude Negroes from sharing in political power. The Civil Rights Act of 1964 established an Equal Employment Opportunity Commission, extended the Commission on Civil Rights and barred job discrimination in federally assisted programs. The act also contained provisions against discrimination and segregation in voting, education and the use of public facilities; and the Negro Voting Rights Act of 1965 was designed to assure Negroes the right to register and vote by, among other provisions, suspending literacy tests used to discriminate against them.

The problem of racial segregation is present in the multiracial communities of central Africa and east Africa but it has been most acute in South Africa. In South Africa the National party has attempted to maintain the dominance of the white minority through the policy of apartheid or racial segregation in the spatial, economic, political and social relations of the races. The white minority had already undertaken to maintain its economic position and social status by a colour bar in industry. The urbanization of the native or Bantu population and the dependence of industry upon native labour tend to nullify the spatial and economic segre-

gation. But the whites have been able through force and the threat of force to exclude the natives and other coloured peoples—Cape Coloureds (*q.v.*) and Asians—from political power, and to maintain a system of racial segregation in all social relations.

Whereas in the United States it appears that racial segregation in the public relations of the races tends gradually to disappear where Negroes offer no threat to the economic and political power of whites, in South Africa racial segregation appears as a desperate attempt on the part of the white minority to maintain its dominance despite the economic and political forces in the situation which are opposed to racial segregation.

SÉGUIER, PIERRE (1588–1672), chancellor of France in the critical period during which absolutism was consolidated. He was born in Paris on May 29, 1588, into a very prosperous family of lawyers. In 1618 he became one of the *maîtres des requêtes de l'hôtel*, the body from which the intendants (*q.v.*) were mostly recruited; and in 1621 he was appointed intendant, first for Auvergne, then with the army in Aunis and Saintonge. In 1624 he succeeded his uncle, Antoine Séguier, as one of the presidents in the Parlement (*q.v.*) of Paris.

The chancellor (*q.v.*) in France was an irremovable dignitary; but if a chancellor displeased the royal government, he could be relieved of his functions by a keeper of the seals. Séguier succeeded the marquis de Châteauneuf (Charles de l'Aubespine) as keeper of the seals in 1633 and became chancellor on the death of Etienne d'Aligre in December 1635.

Industrious subservience to the cardinal de Richelieu (*q.v.*) kept Séguier in function. In 1637 he directed the enquiry into the Affair of Val de Grâce, which compromised the queen of France, Anne (*q.v.*) of Austria. In 1639 he was, extraordinarily, sent to supervise the repression of the revolt of the *Va-nu-pieds* in Normandy. In 1642, at Lyons, he presided over the trial of Cinq-Mars (*q.v.*).

When Richelieu died (1642), Séguier succeeded him as official "protector" of the Académie Française, the sessions of which thereafter took place in his house. To the surprise of many, he was retained in function by Anne of Austria when she became regent for the child Louis XIV in 1643. Serving Cardinal Mazarin (*q.v.*) as he had served Richelieu, he was hated by the malcontents in the Parlement and by the populace. During the Fronde (*q.v.*), he was assailed by a mob in Paris in August 1648; Anne was obliged to transfer the seals back to Châteauneuf in 1650; and though Séguier recovered the seals after the momentary replacement of Châteauneuf by Mathieu Molé (*q.v.*) in April 1651, they were given to Molé again in September. In the last phase of the Fronde in Paris, Séguier was aligned with the rebel princes till August 1652. On Molé's death (1656) the seals were restored to Séguier.

Under the personal rule of Louis XIV, Séguier in December 1662 was put in charge of the trial of Nicolas Fouquet (*q.v.*), which he conducted brutally enough to secure a verdict against Fouquet. From 1665 he presided over the new Council of Justice for the reform of the legal system: though this was in fact dominated by J. B. Colbert, the detail of the Civil Ordinance or "Code Louis" (1667) and of the Criminal Ordinance (1670) owed much to Séguier.

Séguier died at Saint-Germain on Jan. 28, 1672. His voluminous papers are preserved partly in Paris, partly in Leningrad (numerous manuscripts were taken to Russia by the diplomat P. Dubrovski in 1800). The Leningrad papers were exploited by the Soviet historian B. F. Porshnev for his work on "Popular Risings in France before the Fronde" (1948), in which he sought to interpret 17th-century France solely in terms of "the class war." This gave rise to a resonant controversy between Porshnev and the French historian Roland Mousnier, whose monumental *Lettres et Mémoires adressés au chancelier Séguier, 1633–1649*, appeared in 1964.

SÉGUR, SOPHIE ROSTOPCHINE, COMTESSE DE (1799–1874), Russian-born French writer of famous books for children. Born at St. Petersburg on July 19, 1799, the daughter of Fedor Rostopchin (*q.v.*), she became a member of the French nobility through her marriage to Eugène, comte de Ségur, in 1819. In Paris she wrote several volumes for the *Bibliothèque rose*, a popular series of children's books started in the mid-19th century by the publisher Hachette. These were based on stories told to her children and grandchildren, with whom she was unable to play because she had become an invalid. The central character of many of her stories is "Sophie," a young girl whose trials and tribulations are related in a simple prose that is eminently suitable for reading aloud (*e.g.*, *Les Malheurs de Sophie*, 1859). Other favourite volumes, especially among French children, include *Nouveaux Contes de fées* (1857), *Mémoires d'un âne* (1860), and *Après la Pluie le beau temps* (1871). She died in Paris on Feb. 9, 1874.

BIBLIOGRAPHY.—J. Chenevière, *La Comtesse de Ségur, née Rostopchine* (1932); A. de Pitray, *Sophie Rostopchine, comtesse de Ségur, racontée par sa petite-fille* (1939); M. de Hédouville, *La Comtesse de Ségur et les siens* (1953).

SEGURA, a river of southeast Spain, rises in the Sierra de Segura and flows east for 212 mi. (341 km.) through the driest region of the Iberian Peninsula to enter the Mediterranean south of Alicante. Much water is drawn off from the Segura and its major tributary the Guadalentin (Sangonera) to irrigate the *huertas* (market gardens), especially the Vega de Murcia. Winter floods are notorious on both rivers but during the summer the stream beds are almost dry. Eight dams are being built to control the runoff, the largest being at Fuensanta. About 300,000 ac. (more than 121,000 ha.) are irrigated or under development, with further plans for irrigation on the Cartagena plains. (J. M. Ho.)

SEHESTED, HANNIBAL (1609–1666), Danish statesman who laid the foundations of a modern administrative system in Denmark, was born at Arensborg Castle on the island of Ösel (now Saaremaa). Educated at Sorø Academy he traveled abroad from 1629 to 1632, and on his return to Denmark was attached to the court of Christian IV. In 1635 he conducted the unsuccessful negotiations with the Swedish chancellor Axel Oxenstierna for an alliance with Sweden. Soon one of the favourites of Christian IV, in 1642 Sehested married the king's daughter Christiane. He became a member of the *rigsraad* in 1640, and in 1642 was appointed *statholder*, or viceroy, of Norway. There he displayed great energy in developing Norway's material resources and reorganizing its armaments and fiscal system, intending to make Norway more independent of Denmark.

During Christian IV's second war with Sweden (1643–45) Sehested invaded Sweden several times and defended Norway from attack. After the Peace of Brömsebro (1645) he continued to develop Norway's resources and during the years 1646–47, with Christian's support, he obtained for Norway partial control of its own finances. The revenues were used to cover the expenses of the Norwegian militia and to pay off the war debt. Sehested's

success and his personal accumulation of money and honours, however, aroused the distrust and envy of other members of the *rigsraad*. After the death of Christian (February 1648), Sehested was left without support when charged with embezzlement and peculation, and he was forced to surrender his private property in Norway to the crown. In 1651 he retired from the *rigsraad*, and although Frederick III granted him a pension, Sehested lived abroad from 1651 to 1658.

In the summer of 1657 at the time of the war with Sweden Frederick refused the offer of Sehested's services. During the crisis of the war in 1658 (*see* FREDERICK III, [king of Denmark and Norway]) Sehested was at the headquarters of Charles X of Sweden. In thus seeking the protection of Denmark's worst enemy, Sehested approached the verge of treason, but when he saw that Denmark was successfully resisting the Swedish attacks, he began to work in Sweden for Danish interests. In 1660 Frederick III allowed him to return to Copenhagen, and made him plenipotentiary to negotiate with the Swedes. The Treaty of Copenhagen (May 1660), which saved the honour of Denmark, was very largely Sehested's work. He was also prominent during the crisis in the autumn of 1660 which resulted in the conferring of absolute power on Frederick. The king now trusted him completely. Appointed lord high treasurer (*rigesskatmester*) and councilor of state, Sehested proceeded to lay the foundation of a modernized central administration, establishing boards in the different branches of the government (*see* DENMARK: *History*). He died at Paris on Sept. 23, 1666.

SEHORE, a town and district in the Bhopal division of Madhya Pradesh, India. The town, headquarters of the district, lies near the confluence of the Siwan and Latia streams, 20 mi. W.S.W. of Bhopal on the Bhopal-Ujjain railway. Pop. (1961) 28,489. It became the headquarters of the British agent of the former princely state of Bhopal in 1818. It is an important trade centre, and an annual fair called Hardaul Lala mela is held in December.

SEHORE DISTRICT (area 3,600 sq.mi.; pop. [1961] 754,684) was formed by the merger of the former Bhopal state with Madhya Pradesh. It extends to the eastern margin of the Malwa (*q.v.*) plateau drained by the Betwa river. The soil is mainly black cotton soil; 44% of the total area is arable and 24% under forests. Wheat, jowar, cotton and linseed are the principal crops. There is a heavy electrical equipment plant at Bhopal (*q.v.*), the capital of Madhya Pradesh. Other industries include cotton textiles, sugar, paper and straw products. (S. M. A.)

SEICHE, a free oscillation of fluid in an enclosed or semi-enclosed basin. The word originated centuries ago (supposedly from Lat. *siccus*, "dry," hence exposed) to describe the occasional tidelike rise and fall of water at the narrow end of Lake of Geneva, Switzerland. Its rhythmic movement was noted first by N. F. de Duillier (1730); that it was common to other lakes and related to atmospheric conditions was observed by Jean Pierre Vaucher (1803). But to F. A. Forel (1869–95) belongs the credit for recognition of its essential character and origin. Forel's classic work incited continuing observational and hydrodynamic studies of lake and sea oscillations of which G. Chrystal's (1904–09) are most noteworthy. Refinements to Chrystal's theory were contributed by A. Defant (1929) and J. Proudman (1953).

Forel recognized that a pure lake seiche is in effect an interaction of two equal long waves, traveling in opposite directions. Their resultant is a standing wave that remains fixed in position while the water surface seesaws about nodal line or lines, at still water level. Between nodes, peaks and troughs are known as antinodes. If the distance between antinodes is a multiple or submultiple of the length of the lake (for uniform depth), the standing wave fits exactly into the length. It is then capable of resonating since repeated reflections contribute additional synchronous standing waves which accumulate amplitude. Only bottom friction and viscous turbulence prevent indefinite amplitude-growth. Such a resonant standing wave system constitutes a seiche. Equal opposing progressive waves, that are not commensurate with the lake length, produce interfering standing waves, on repeated reflection, tending to annul each other. Thus when the water in a basin is disturbed, incommensurable wave motions die out rapidly while commensurable ones develop as persistent seiches.

The fundamental seiche in a closed basin is uninodal. Forel discovered that binodal, trinodal and other multinodal seiches were often coexistent with the fundamental. These several modes of oscillation are higher harmonics of the fundamental seiche, the binodal seiche, for instance, being second harmonic. The periods of harmonics (time intervals between successive antinodal peaks) are usually integral submultiples ($\frac{1}{2}$, $\frac{1}{3}$, . . .) of the period of the fundamental; departure from this is a feature of irregular, variable-depth basins. Periods of seiches depend exclusively on basin-dimensions and mode of oscillation. As examples, the fundamental, second and third harmonic periods of Lake Constance (Switz.) are 55.8, 39.1 and 28.1 min.; of Loch Earn (Scot.) 14.5, 8.0 and 6.0 min. Lake Erie has a fundamental period of 13.1 hours; the Aral Sea 22.8 hours. In general, periods are proportional to basin length L, and inversely proportional to the square root of water depth d.

Unlike lakes, coastal bays and inlets require the node of any seiche to be at the mouth where the basin communicates with a larger body of water. The even harmonics of such basins are normally suppressed and periods thus tend to the harmonic order of 1, $\frac{1}{3}$, $\frac{1}{5}$, ...

An important property of pure seiches is that water-particle movements are all linear synchronous oscillations. At the nodes surge movements are horizontal, and greater in range than the antinodal vertical range by a factor of $L/\pi d$. At the antinodes, heaving movements are entirely vertical. Between these extremes, magnitudes and directions change gradually.

Seiches tend to develop in bodies of water during or after imposition of agitating forces. Forel, Chrystal and others identified forms of excitation as (a) release of pent-up water at a leeward shore through lapse of onshore winds, (b) heavy rain, snow or hail over a portion of a lake, (c) rapid change of air pressure through passage of a squall, (d) flood discharge from rivers at one end of a lake, (e) impacts of wind gusts on the water surface, (f) disturbances from earth tremors (*see* EARTHQUAKE). More gradual energizing sources are (g) variations in wind velocity and pressure and (h) passage of small barometric fluctuations, both synchronizing approximately with seiche periods.

Seiches in certain coastal ports have caused ships to break moorings and sustain damage under action of nodal surge currents. Such seiches are usually of two distinct kinds: those of fairly long period (15 to 60 min.) attributable to (h), and those of much shorter period (0.3 to 15 min.) attributable to ingress of long period waves originating from distant cyclonic storms through causation (g). "Surf beats" afford another mechanism for coastal seiches as result of greater water transport shoreward from groups of high waves than from groups of low waves.

Internal seiches at the stratified interface (thermocline) of lake waters were discovered by E. R. Watson and E. M. Wedderburn (1904–12). Amplitudes are larger than surface seiches and periods longer—Lake Baikal, for instance, has an internal seiche period of 38 days, amplitudes up to 75 metres.

See J. Proudman, *Dynamical Oceanography* (1953); Basil W. Wilson, "Origin and Effects of Long Period Waves in Ports," *Communication 1, Section II, XIXth International Navigation Congress, London, 1957* (1957). (B. W. W.)

SEIGNIORAGE is in general a term denoting something claimed or taken by virtue of sovereign prerogative. Specifically, it is the charge over and above the expenses of coinage, or brassage, deducted from the bullion brought to a mint to be coined. From early times coinage was the prerogative of kings, who prescribed the total charge and the part they were to receive as seigniorage. Seigniorage, as a royal revenue, was varied according to the sovereign's caprice, avarice, or necessity. The deduction was sometimes supplemented by replacing part of the bullion with base metal, resulting in debased coinage. As the seigniorage and coinage charges were collected by withholding part of the bullion brought for coinage, the currency value of

the coins received in exchange was often less than the bullion's market value. In consequence, merchants did not bring bullion to the mint and the supply of coins was inadequate. In England, therefore, all charges for coinage were abolished in 1666.

From early times coins of gold or silver had an intrinsic value close to their face value. In fact, as pieces of bullion of guaranteed weight and fineness, they served as a medium of international as well as internal exchange. Nowadays, bills of exchange and bank notes perform this function, and coins are merely token money, issued for domestic purposes only. Thus, coins need no longer possess a high intrinsic value, and low-standard silver or certain base metal alloys provide all the qualities required. A substantial margin usually exists between the cost of producing a coin and its statutory currency value; this margin or profit is known as seigniorage. (H. G. St.)

SEINE, the second longest river of France (482 mi.) and economically the most important, rises on the Plateau de Langres 18 mi. NW of Dijon, and reaches the English Channel in a wide estuary which passes between Le Havre and Honfleur. With its several large tributaries, it represents a relatively mature river system, with gentle gradients throughout. It has a drainage area of more than 30,000 sq.mi. and for most of its course flows transverse to the general geological structure of the Paris Basin. Since it rises on Jurassic (Oolitic) limestone (at about 1,500 ft.), the uppermost part of its course is not permanent, and in dry summers the valley may be dry as far down as Châtillon, where it leaves the limestone and crosses a narrow strip of Oxford clay. It then enters a narrow wooded valley through the escarpment of the Corallian limestone; the valley widens temporarily at the succeeding outcrop of Kimmeridge clay, where the Ource River enters from the east. At Bar-sur-Seine, the river cuts through the Portland limestone, beyond which it enters the broad lowlands of *Champagne humide* (mainly the outcrop of the Gault clay), before encountering the Chalk escarpment at Troyes. The course then follows a broad entrenched valley across the chalk area, *Champagne pouilleuse*, until it is joined by its right-bank tributary, the Aube River (*q.v.*). From there the Seine follows a southwesterly direction at the foot of the Tertiary escarpment to Montereau, where the Yonne River joins it, and then passes into the Tertiary limestone uplands, which rise in steep wooded hillsides 200–300 ft. above the river. From there to the sea, the Seine receives only minor left-bank tributaries, but larger rivers such as the Marne (at Paris) and the Oise on the right. Below Paris, the river begins its series of huge swinging meanders, and gradually reencounters the Chalk, which appears as cliffs wherever the valley sides are undercut by the river. The meanders add about 120 mi. to the direct distance between Paris and Le Havre. Below Rouen, the valley widens with extensive alluvial flats. In the estuary, which begins near Tancarville (the lowest bridging point), there are strong currents, and a tidal bore associated with exceptionally high tides.

The Seine carries the heaviest tonnage of shipping of all the French rivers; the most important section is Le Havre-Rouen-Paris. The lower-middle course of the river has a regular regime resulting from the large drainage area. Low water occurs in summer, while the maximum discharge is in winter and early spring, aided by snow melt and reduced evaporation losses. The concentration of several large rivers in the Paris district brings the danger of winter flooding. The approximate maximum discharge at Paris is about 100,000 cusecs. The head of navigation is at the Aube confluence, though from there upstream to Troyes a lateral canal provides a minimum depth of 5 ft. Between Paris and the Aube confluence, there are numerous cuts to straighten the river, and 39 locks maintain a minimum depth of 6.5 ft. At Paris, the minimum depth increases to 9.8 ft. Rouen can receive sea-going craft with 25 ft. draft at mean high-water springs. Below Tancarville, river craft tend to use the canal to Le Havre to avoid the strong currents of the estuary. The Seine is linked by canal with the Somme, Scheldt (Escaut), Meuse, Rhine, Saône, and Loire rivers.

Paris is the third largest French river port (after Rouen and Strasbourg). The river port begins at Nanterre, and wharves and quays extend upstream for more than 25 mi. Within Paris the river is divided by several islands, and the 27 bridges of the city are a serious obstacle to some ships at high water. The main incoming traffic consists of coal, iron and steel, building materials and agricultural produce. Rouen is the outport of Paris, 145 river mi. downstream; oil and coal are the principal imports, the former proceeding to the important Shell refineries there. Le Havre on the north shore of the Seine estuary is capable of handling large ocean-going liners, and possesses shipbuilding and engineering industries. (C. Em.)

THE SEINE ALONG QUAYS OF THE ÎLE DE LA CITÉ, PARIS. THE RIVER DIVIDES INTO TWO ARMS AROUND THE ISLAND

SEINE-ET-MARNE, a *département* of northern France formed in 1790 from parts of the Île-de-France and Champagne, and surrounded by the *départements* of Oise to the north, Aisne, Marne, and Aube to the east, Yonne and Loiret to the south, and to the west by Essonne, Val-de-Marne, Seine-Saint-Denis, and Val-d'Oise, four of seven new *départements* created in 1964 from the former Seine and Seine-et-Oise. Seine-et-Marne itself has not been altered in the regrouping of administration areas in the metropolitan region. Area 2,286 sq.mi. (5,917 sq.km.). Pop. (1962) 524,486. The *département* lies east of Paris, near the heart of the Paris Basin, and is traversed by the great valleys of the Seine and Marne rivers as they converge toward Paris. Between the two main valleys lies the Tertiary limestone platform of Brie, dissected by the Grand Morin, Petit Morin, Yerres (Yères), and other tributaries of the Seine and Marne. North of the Marne valley stretches the similar limestone platform of Valois, but south of the Seine are sandy tracts traversed by the Loing River. On its left bank as it approaches the Seine is the forest of Fontainebleau, occupying the park of an old royal palace, much frequented now by Parisians. On its right bank another infertile sandy area, the Gâtinais, extends toward the Yonne River. Elsewhere the *département* consists of rich farmlands and, in spite of its proximity to the capital, it remains primarily agricultural. The grainfields of the limon-covered limestone platforms have long supplied Paris. Wheat and sugar beet are the main crops, with oats, potatoes, and green fodders also important, and a heavy density of livestock is maintained on the large farms. Brie cheese is well known and is made especially at Meaux and Melun. The river valleys are lined with lush meadows, market gardens, and nurseries; and orchards surround the substantial villages at the foot of the steep valley sides. The valley towns are

market centres and river ports that have become the nuclei for residential development and a modest growth of industry. Chief among them are Montereau and Melun on the Seine, Coulommiers on the Grand Morin, and Meaux on the Marne, while in the east, toward Champagne, is Provins. The limestone has been extensively quarried and is much in evidence in local building. In the southwest the Fontainebleau sands have been worked for glass-making, and elsewhere gypsum has been quarried. Melun (*q.v.*) is the *préfecture* of the *département*, which is divided into three *arrondissements*, centred upon Melun, Provins, and Meaux. It forms the diocese of Meaux, and comes under the court of appeal as well as the *académie* of Paris. (AR. E. S.)

SEINE-MARITIME, a *département* of northern France, formed in 1790 from the eastern part of the ancient province of Normandy. Pop. (1962) 1,035,844. Area, 2,449 sq.mi. (6,342 sq.km.). The *département*, formerly called Seine Inférieure, includes the mouth of the Seine and its lower valley below Elbeuf, together with the districts along the English Channel coast to the east. It is bounded east by the *départements* of Somme and Oise, and south by Eure. The Seine, approaching its estuary, flows in sweeping meanders which cut across rolling chalk plateaus. The main river valley and the side valleys that wind back into the plateau are heavily industrialized, forming the Rouen textile region, but the chalk plateau to the north, the Pays de Caux, remains basically agricultural. The chalk is extensively covered with fertile *limon* and is largely arable, devoted especially to wheat and sugar beet. Potatoes are important and some flax is still grown. Behind Dieppe the chalk has been breached in an anticlinal structure to expose the underlying clays along the Béthune Valley. This diversified district, the Pays de Bray, has rich pastures that support dairy farms and is well known for its cheese. The farming country of eastern Normandy for the most part turns its back upon the sea, which is fronted by high chalk cliffs, but there are some fishing ports, notably Fécamp (*q.v.*), which is engaged in distant trawling as well as in herring fishing, and resorts such as Le Tréport and Yport, while Dieppe (*q.v.*) provides an important passenger link across the Channel with England (via Newhaven). Rouen (*q.v.*), situated at the lowest bridging point on the Seine, although it is 90 mi. (145 km.) upstream from the sea, is still an important port. Le Havre (*see* HAVRE, LE), created in 1517 as a planned town on the alluvium that flanks the north coast of the Baie de la Seine, has developed as the deepwater port of this ocean gateway of Paris. Besides its great commercial docks, it has an important shipbuilding industry and engineering and chemical works. The strip between Le Havre and Rouen has become the major area of oil refining in France, with large refineries at Gonfreville, Gravenchon, Port-Jérôme, and Le Petit-Couronne, which are connected with Paris by pipeline as well as by the river. The old established textile industry of the lower Seine, centred upon Rouen, has become especially concerned with cotton goods, its raw material imported through Le Havre, but Elbeuf (*q.v.*) is important for woolen manufacture, and the new man-made fibres are also represented.

Rouen, the historic capital of Normandy, is the *préfecture* of the *département*, which is divided into three *arrondissements* (Rouen, Le Havre, and Dieppe), and is the seat of its court of appeal. The *département* forms the diocese of the archbishop at Rouen, but for educational administration comes under the *académie* of Caen. The ports and towns suffered severe damage from bombardment during World War II, which took toll of Rouen's fine Gothic architecture as well as of modern housing and factory buildings. Apart from its magnificent cathedral, the law courts and the church of Saint-Ouen are especially noteworthy at Rouen, which also has many art treasures. Among several fine monastic buildings in the *département* are St. Martin-de-Boscherville, Valmont, Montivilliers, and Jumièges. The castle of Tancarville occupies a commanding site on a promontory overlooking the Seine Valley. Varengeville has the beautiful Renaissance manor house of Jean Ango (*see* MANOR HOUSE). (AR. E. S.)

SEINE-SAINT-DENIS, a *département* of France formed in 1964 of the northeastern part of the former *département* of Seine, together with Aulnay-sous-Bois and Le Raincy, which formed the northern part of the corridor of Seine-et-Oise that separated the Seine and Seine-et-Marne *départements*. Bounded east by the *département* of Seine-et-Marne, south by Val-de-Marne and Ville de Paris, west by Hauts-de-Seine, and north by Val-d'Oise, it comprises the northward and eastward extensions of Paris outside the line of the 1841–45 fortifications. Area, 91 sq.mi. (236 sq.km.). Pop. (1962 census of 1964 units) 1,083,724. The *département* is heavily urbanized, except in the extreme northeast beyond the airport of Le Bourget, where cornfields still lie close to Paris.

Beyond the northern gates of Paris, the flat plain of Saint-Denis was occupied during the 19th century by factories, housing, and a close mesh of lines of communication. The canals and railways that converge to enter Paris by the col between the hills of Montmartre and Chaumont are lined with establishments of heavy industry, especially chemical and engineering works, and gas and electric power stations; and a great variety of other factories are closely intermingled with workers' housing in the communes of Saint-Denis, Aubervilliers, and Pantin that lie immediately outside Paris. In this inner zone a large cemetery between Pantin and Aubervilliers provides the chief open space. Factories and various types of housing extend in more open association in La Courneuve, where the *préfecture* has been established, and Le Bourget, and market gardens have not altogether disappeared from these northern suburbs. In the west the *département* reaches the Seine at the tip of its meander, where it is joined by the Saint-Denis Canal, which bypasses the great loop of the river below Paris. The river and canal banks are crowded with port installations and factories, making Saint-Denis (*q.v.*) one of the major concentrations of industry in Greater Paris. Beyond Pantin, a compact belt of housing and industry extends eastward along the Canal de l'Ourcq and the historic road (N3) to Lorraine, but south of this the hilly country that occupies the southeast of the *département*, north of the Bois de Vincennes and the Marne valley, has been the scene of more open, predominantly residential development. Dormitory suburbs have rapidly expanded there since World War I.

The northern industrial suburbs of Paris in Seine-Saint-Denis suffered severe aerial bombardments by the Allies during the German occupation. (AR. E. S.)

SEIPEL, IGNAZ (1876–1932), Roman Catholic priest who was chancellor of Austria from 1922 to 1924 and from 1926 to 1929. He was born in Vienna on July 19, 1876. Ordained priest in 1899, he was appointed professor of moral theology at Salzburg University in 1909 and was called to Vienna University in 1917. In 1916 he had published *Nation und Staat*, in which he advocated cultural autonomy within the existing political structure for the various nationalities of Austria-Hungary and also gave expression to a moderate pacifism. Publication of these views led to his being chosen for a post in Heinrich Lammasch's government (Oct. 27, 1918). After the collapse of Austria-Hungary at the end of World War I, he prevented the Social Christian Party, to which he belonged, from splitting between monarchists and republicans. Elected to the Constituent Assembly (1919), he entered Karl Renner's coalition government. Party leader of the Social Christians from 1921, he ended their coalition with the Socialists and brought them into alliance with the Pan-Germans.

Seipel formed his first government on May 31, 1922. His personal diplomacy obtained for Austria a loan of $100,000,000 through the League of Nations; but the Geneva Protocols of Oct. 4, 1922, on which the loan was conditional, were bitterly criticized by the Socialists. Though the loan served to stabilize the Austrian currency and to balance the budget, the economy remained unsound, and Seipel's efforts to restore it met with objections from provincial governments and led to dissension within his own party. On June 1, 1924, he was severely wounded by a shot from a labourer. Seipel resigned office on Nov. 7, 1924.

Chancellor again from Oct. 20, 1926, Seipel hoped to confirm his mandate by holding an election in April 1927. The result went against him, but he reshaped his cabinet and remained in office. The Socialists' rioting in Vienna (July 15, 1927) started a period of strife in which Seipel tried to use the Fascist *Heimwehr* against the Socialists' *Schutzbund*. He resigned on April 3, 1929.

In *Der Kampf um die österreichische Verfassung* (1930) Seipel

argued for a reform of the constitution that would establish a corporate state with a federal president elected by national suffrage and endowed with greater powers. He himself sought to become president in 1930, but his party did not support him. He was foreign minister in Karl Vaugoin's cabinet of Sept. 10–Nov. 29, 1930. Seipel died at Pernitz on Aug. 2, 1932. (H. Pf.)

SEI SHŌNAGON (966/967–1013?), Japanese diarist and poet, a witty and learned member of the court, whose *Pillow-Book*, apart from its high value as the vehicle of one of the most original and scintillating Japanese prose styles, is the best modern source of information on Japanese court life in an unusually brilliant period. She was the daughter of the poet Kiyohara no Motosuke and in 991 entered the service of the empress Sadako. Her *Pillow-Book* begins in that year and continues until the year 1000. It consists in part of vividly recounted memoirs of Sei Shōnagon's impressions and experiences, in part of such categories or judgments as "Annoying Things" or "Things Which Distract in Moments of Boredom."

Sei Shōnagon was apparently not a beauty, but managed to hold her place at court by virtue of her ready wit and intelligence, qualities that won her numerous enemies as well, as is witnessed by a passage from the diary of her contemporary, Murasaki Shikibu (*q.v.*). Although capable of great tenderness, Sei Shōnagon was often merciless in the display of her wit, and she showed little sympathy for those unfortunates whose ignorance or poverty rendered them ridiculous in her eyes. Her ability to catch allusions or to compose in an instant a verse exactly suited to a particular occasion also led her to affect, if her detractors can be believed, an air of superiority that others found intolerable. Perhaps by way of poetic justice, legends state that Sei Shōnagon spent her old age in misery and loneliness.

Bibliography.—Arthur Waley, *The Pillow-Book of Sei Shōnagon* (1928); André Beaujard, *Les Notes de Chevet de Séi Shōnagon* (1934) and *Séi Shōnagon, son temps et son oeuvre* (1934). (Dd. K.)

SEISIN, a term from medieval English land law, of little modern significance, signifying possession of a freehold estate. Seisin was basic in the feudal theory of estates (*see* Real Property and Conveyancing, Laws of). The old form of conveyance, known as feoffment with livery of seisin, required a symbolic delivery of possession by handing the transferee a clod of earth, a twig or the like. *See* Feoffment. (A. Dm.)

SEISMOLOGY, the study of vibratory motions of the earth and other planetary bodies. A branch of geophysics (*q.v.*), seismology originated in the study of earthquake waves, but later was enlarged in scope to include vibratory motions due to other sources, including explosive charges. Records of the vibratory motions are made by seismographs; the principal types and their uses are described in a separate section, below. These records are carefully studied and compared to learn about the nature of earthquakes, and to obtain knowledge about some of the physical properties of the earth's interior. Both of these are possible in principle, since recordings at a seismic observatory represent the influence of the event at the earthquake focus, as well as the influence of the path through the interior of the earth over which seismic energy has been communicated to the seismograph. The properties of the seismograph are further impressed upon the recording, but this represents an influence which is presumed to be known.

Sources of Vibrations.—Sources of vibrations of the earth sufficient to cause measurable response upon sensitive seismographs include earthquakes, man-made explosions, volcanic eruptions, microseisms, the influence of wind upon surface structures, and, in urban areas, traffic. Microseisms are largely the vibratory motions due to storms at sea; the principal cause is differential loading of the ocean floor by large waves in the deep sea, and a secondary cause is the breaking of surf upon shore. For the purpose of interpreting earth structure, earthquakes and artificial explosions are most useful, since the focus of their occurrence can be located more or less accurately, and, as they are impulsive in character, a discrete time of occurrence can be ascribed to them. The remaining types of sources assume the character of a background "noise"; it may be possible to study seismic events of interest, such as earthquakes and explosions, if these events are recorded sufficiently strongly above the noise level.

Detectors.—Seismic recordings are made by seismographs (*see* below). Seismic instruments have varying characteristics that are specially selected in order to study features of seismic waves of interest. Pendulum seismographs are usually separated into short and long period instruments; the separation between these two classes of instruments is usually gauged by the relatively narrow band of periods in which microseismic energy is strongest; microseisms will usually mask earthquake recordings made in this band. Instruments having sensitivities at periods longer than 6 to 8 sec. are called long-period instruments; short period instruments have their greatest sensitivity at periods shorter than 6 sec. Geophones, or seismometers used in prospecting for oil and in some crustal studies, have their greatest sensitivities at periods of the order of .01 to .1 sec. in order to detect the motion of the earth due to the high frequencies obtained in the artificial explosions used in this type of work. Strain seismographs and gravimeters are seismic instruments with very long period responses. Part of the purpose of restricting the band of observable frequencies is to improve as much as possible the ratio of desirable signal energy due to earthquakes or explosions to noise energy due to microseisms, traffic, and other noise sources.

SEISMIC WAVES

Waves emitted from a seismic source fall into two main categories; each of these categories is further divisible into several types. One category is that of body waves, and these are of two main types, each of which travels with a different velocity. The body wave with the higher velocity is a compressional motion and is called a primary, or P, wave. The motion of the particles of the earth in a P wave is longitudinal or parallel to the direction of propagation. The secondary, or S, body wave has a shear motion, transverse to the direction of propagation. The velocity of S waves is always less than that of P waves at the same point. Thus an S event on a seismograph always follows the P event in time, and the farther the seismograph from the focus of the earthquake, the greater the time interval between the P and S events.

In general, the increase in velocity with depth in the earth causes the ray path of body waves to be curved (fig. 1). In addition to P and S waves that travel directly from the focal point of the earthquake along curved paths to the seismograph, other seismic events can be observed since, wherever discontinuities in physical properties exist in the earth's interior, reflection or refraction of body waves can take place, analogous to the reflection and refraction of light (*see* Refraction). Conversion from P to S motions and the reverse can take place upon reflection, as well as reflections without change of wave type. Thus a wave traveling downward from the earthquake focus as P will reflect off the core boundary as both S and P. These will appear on the seismogram as later events, labeled PcS and PcP, where the labels indicate the history of the event, with PcP occurring before PcS. From the multiplicity of events recorded on a seismogram for a single earthquake, considerable information can be obtained concerning the nature and subsequent history of the event.

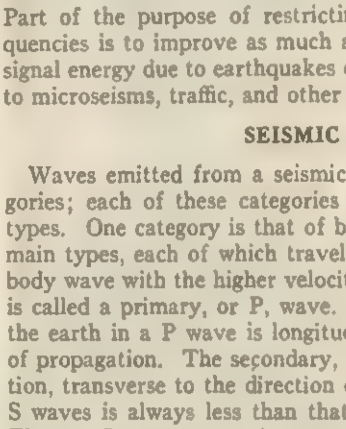

FIG. 1.—SOME OF THE PATHS FOLLOWED BY EARTHQUAKE WAVES. WITH A SCHEMATIC REPRESENTATION OF A SEISMOGRAM WITH BODY (P, S) AND SURFACE WAVES

The second main category of seismic waves is that of surface waves. In this case the seismic energy is propagated around the surface of the earth rather than through the body of the earth. Surface waves are of several types. Among the principal types are Love waves in which the particles vibrate parallel to the surface of the earth, and Rayleigh waves in which the particles move in vertical planes containing the great circle paths from epicentre to seismographs. (The existence of these waves had been predicted by A. E. Love and Lord Rayleigh, respectively.) Surface

wave energy generally diminishes with increasing depth, most of it being found within a depth of the order of the wavelength of the surface waves.

Surface waves are dispersed due to inhomogeneity in the earth's interior so that surface waves with different periods travel with different velocities. Rayleigh waves of 30-sec. period travel faster than do those of 20-sec. period, for example, and will appear earlier on the seismogram (*see* fig. 2).

On a seismogram showing both body and surface waves, the body waves show abrupt onsets. The surface waves show no sharp onsets, because the different frequency components of these waves travel with different velocities. The amount of the dispersion of surface waves is diagnostic as to the distance from the earthquake focus and as to the type of inhomogeneity in the earth.

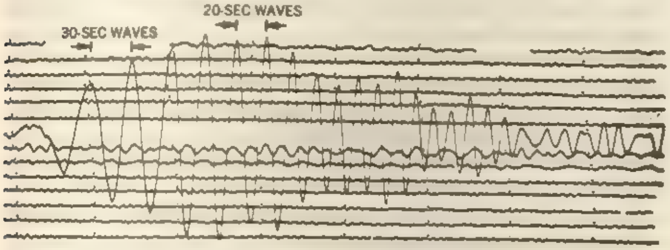

FIG. 2.—LONG-PERIOD SEISMOGRAM FOR THE MID-NORTH ATLANTIC OCEAN EARTHQUAKE OF OCT. 6, 1960, RECORDED AT CHUR, SWITZ., ILLUSTRATING DISPERSED RAYLEIGH WAVES

Abrupt onsets are characterized by large amounts of high-frequency constituents; hence, body waves are easily identified on short-period instruments. Surface waves can be more easily studied on long-period instruments because the dispersion is usually greatest for the crust and upper mantle in the long-period band.

See also EARTHQUAKE: *Earthquake Waves.*

SEISMOLOGICAL STUDIES

Seismologists study the recordings from earthquakes and explosions with several main purposes in mind. First, they wish to study the nature of the earthquake mechanism. From studies of seismograms, inference is made as to the characteristics of the source and the focal mechanism.

A second purpose is to use the seismic energy which has passed through the earth's interior as a means for studying the degree of heterogeneity of the earth's interior. Comparative studies of recordings from many stations to determine the changes in the seismic records from station to station, representing the influence of different parts of the earth on seismic waves, can lead to information about the structure of the earth. (*See* EARTH: *Structure of the Interior: Seismic Exploration;* GEOPHYSICAL PROSPECTING: *Seismic Methods.*)

Times of Arrival.—Universal time-distance relations have been constructed from compilations of the observations of many observatories upon the times of arrival for many earthquake waves. These relations indicate the time of travel of earthquake waves of any type from an earthquake focus to an observatory. From the time interval between the abrupt onsets of P and S events on a single seismogram, the distance to the impulse-source can be estimated by comparison with the universal time-distance relations. By comparison of the events recorded on a set of three-component seismographs at one observatory, the direction of the source can be located in principle. The times of arrival of later body wave events lend substantiation as to the location. The comparison of times of arrival at many observatories leads to a more accurate determination of the location and depth of the focus of the earthquake.

From the universal time-distance relations it is possible to compute the distribution of P and S wave velocities in the interior of the earth. The time-distance relations for the body events that arrive at times later than P and S give additional information about the depths and properties of inhomogeneities at great depth in the earth. The P and S wave velocities generally increase with depth to 2,900 km. (1,800 mi.) where a marked discontinuity in properties is found to exist. This discontinuity provides a horizon for reflections. No S waves have been found to penetrate the region below 2,900 km., called the core of the earth; since liquids cannot be sheared or twisted, the core is presumed to be liquid. Other discontinuities have been found at greater and at shallower depths. Gradual changes in physical properties with depth are found from the interpretation of times of arrival.

Mohorovičić Discontinuity.—The Mohorovičić discontinuity, moho, or "M," marking the lower boundary of the earth's crust, was discovered by Serbian geophysicist A. Mohorovičić. In his studies of an earthquake in the Balkans in 1909 he observed that travel-time curves determined from the recordings made by nearby seismograph stations showed an abrupt increase in seismic velocity occurred at a depth he estimated to be about 60 km. (37 mi.). From this he postulated the existence of a surface layer, now called the crust, covering the earth's mantle. Subsequent investigations have indicated that the depth of this discontinuity is 7 km. (4 mi.) on the average under the oceans, and about 40 km. (25 mi.) on the average under the continents, as indicated below.

Surface Waves.—Additional detail about the properties of the earth's interior is obtained from the analysis of the dispersion of surface waves. The times of arrival of different periods of surface waves can be interpreted with the aid of mathematical models to give estimates of the P and S wave velocity variations and the density variation with depth of the upper parts of the earth. Because of the many modes in which surface waves can propagate, the versatility of this method of interpretation of the structure is great. The differences in times of arrival for a given period of surface waves at neighbouring observatories can be used to study the structure of the upper parts of the earth between the observatories.

Focal Mechanism Studies.—In addition to studying the location of the earthquake focus, both geographically and in depth, and indicating the times of occurrence, studies of records taken at observatories remote from the focus can indicate the characteristics of the earthquake at the focus. In one example of this type of work, the direction of motion of the seismometer upon the onset of a P wave can be used to determine the orientation of the earthquake fault upon rupture. Assume that we take for our model of an earthquake the abrupt relative motion of two blocks of the earth abutting upon a plane which we call the fault plane of the earthquake (fig. 3). When the blocks abruptly slip, the material in both regions A and C is initially compressed, and in regions B and D is initially dilated or expanded. Thus at observatories located in region A and at points remote from the earthquake, the onset of the P event will appear to move in a direction away from the earthquake focus. Similar conclusions can be drawn from observatories in the other quadrants. If observatories all over the world are polled as to the direction of the first observed motions of P, some stations will report initial compressions and some initial dilatations. The stations reporting dilatations and compressions will distribute themselves into quadrants on a map; one of the lines of separation of the quadrant is then the projection of the fault plane onto the map. Unfortunately, the solution is not unique, since a hypothetical fault plane oriented at right angles to the first and undergoing initial displacements opposite in sense to the first will show the same distribution of compressions and dilatations. A resolution of this ambiguity comes from other evidence such as the distribution of aftershocks or geologic evidence. The distribution of first motions of S as recorded at many observatories can also be mapped, although some difficulty is connected with this procedure since the onset of S is often not clearly

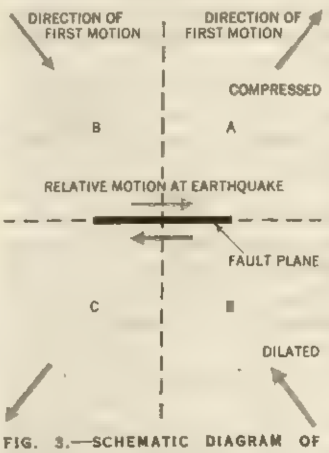

FIG. 3.—SCHEMATIC DIAGRAM OF THE RADIATION OF THE FIRST MOTION OF P WAVES FOR AN EARTHQUAKE FAULT

discernible in the presence of the oscillatory motion subsequent to the onset of P. By the above procedure, however, observations taken from remote observatories can be used to help determine the orientation of the fault plane of the earthquake.

In the case of an explosive seismic source, every observatory should move initially in a direction away from the focus. Thus all stations should report initial compressions; no quadrant separation between dilatations and compressions should be possible. This difference has been suggested as one diagnostic test for distinguishing between underground explosions and earthquakes.

The velocity of rupture of earthquake faults can be measured by studying the surface wave energy arriving at an observatory in various frequency bands. The predominance of energy at one frequency and absence at another can be interpreted as an interference phenomenon corresponding to a selection process associated with a moving source. The moving source, in this case, is the point of tear of the fault. In the case of the Chilean earthquake of May 21–22, 1960, the velocity of rupture was found to be 3½ km. (2 mi.) per second, a value roughly the same as the shear velocity for the crustal rocks in which the earthquake took place. This type of observation is possible only for the largest earthquakes.

Structure of the Earth.—Some of the physical properties of the earth can be determined by comparative studies of seismic recordings at several observatories; in some cases only one observatory is required if the assumption is made that the earthquake has certain ideal properties, such as that of being impulsive in time, and that its focus is located at a point in the interior. One example has already been given of the inversion of time-distance data to give the P and S wave velocity-depth relation for the earth.

Several other procedures can be listed; usually several methods are complementary since the results obtained by any one method are not absolutely precise.

The amplitudes of seismic waves at many stations may be compared. This is not always a reliable procedure, mainly because of varying instrumental properties from station to station, as well as a strong dependence of the amplitude of the response upon the type of soil upon which the instruments may be placed. Nevertheless, strong changes in amplitude in the range 11,700 to 15,900 km. (7,270 to 9,800 mi.) from earthquakes gave evidence for the existence of the outer core and later the inner core of the earth. Precise depth determinations of these discontinuities come from analysis of time-distance relations.

Another property that can be determined from the study of amplitudes is the ability of the earth to attenuate seismic waves. If the earth did not have some nonelastic mechanism whereby seismic waves were attenuated, the seismic energy released in earthquakes of the past would still be stored in the earth and the surface would vibrate continuously with very large amplitudes. The comparison of amplitudes on successive recordings at one station, as a surface wave from a large earthquake executes multiple circuits of the earth, leads to estimates of the attenuation factor. For Rayleigh waves the amplitudes are reduced by roughly 2% between two points a wavelength apart.

Other physical properties of interest have been discovered by seismic means, principally from time-distance relationships. Among these are: (1) a region of body wave velocities slightly lower than those above or below, centred at about 100–200 km. (62–124 mi.) below the surface; (2) a marked increase in the body wave velocity gradient at about 400 km. depth; (3) differences in the thicknesses of the crust of the earth between oceans and continents: under the deep ocean bottoms, the crust is 5 to 7 km. thick, while the continental crust is about 40 km. thick on an average; (4) a thickening of the crust under mountains. (*See* also EARTH; ISOSTASY.)

Free Oscillations.—The Chilean earthquake provided the first example of the recording of the free modes of oscillations of the earth, and these were observed by five groups of investigators using strain seismographs, gravity meters, and tilt pendulums. (For discussion and illustration of the recording made with the strain seismograph, *see* EARTHQUAKE: *Earthquake Waves.*) Before that time, observations of the free modes had not been made, principally because sensitive instrumentation had not yet been developed to measure the small displacements at the extremely long periods involved. The existence of the free modes had been predicted some time earlier but the exact values of the period were dependent upon the theoretical models used in the calculation.

The free modes of oscillation are a resonance phenomenon. A cast bell, when struck, rings in a fundamental and a large number of overtones. The relative amplitudes of the fundamental and overtones, the "overtone spectrum" of the bell, depend strongly upon where and how it is struck and where and how it is observed. The periods of the spectrum depend upon the shape and dimensions of the bell and the elastic structure of the bell. Since the earth is highly elastic (its attenuation factor is low as shown above), it too should ring in a fundamental and many overtones when struck, in this case by a large earthquake. From the models of the earth obtained by time-distance observations and from the dimensions of the earth, the longest period of the oscillation was predicted to be about an hour.

Harmonic analysis of the seismograms taken from the Chilean earthquake showed a fundamental of 54 minutes. At least 40 overtones were observed. The overtones could be divided into two groups corresponding to torsional and spheroidal oscillations. These two groups of oscillations correspond, in the torsional case, to the pure twisting of parts of the earth relative to one another without compression or dilatation, and in the spheroidal case, to the coupled compression torsion of parts of the earth relative to each other. In the torsional mode with longest period, one hemisphere is twisted clockwise while the other is twisted counterclockwise, and vice versa. In the lowest spheroidal mode the equator moves radially outward while the poles move radially inward, and vice versa; this is the "football" mode. The words hemisphere, equator, and poles as used here do not correspond to the geographic terms, but instead correspond to coordinates dependent upon the location of the earthquake.

The observed periods of the free modes from large earthquakes strengthen confidence in the use of models of the earth's interior derived from time-distance data. Comparative amplitude studies upon the spectra for the purpose of determining focal mechanism were not performed, because of the small number of observatories participating in the observations.

Planetary Seismology.—Many of the techniques and studies described here can be applied to studies of the planetary bodies in the solar system. The sources can be local quakes upon the body or artificial seismic sources such as explosives. In the case of the moon, measurements are simpler than on earth because of the absence of atmosphere and oceans; hence noise due to microseisms, wind, traffic, etc. is absent. (L. KN.)

SEISMOGRAPHS

Instruments for recording and measuring vibratory movements of the ground are known as seismographs. As indicated above, their use originally was restricted to movements produced by earthquake waves. Subsequently special types have been devised to record ground movements produced by artificial blasts for location or delineation of subsurface geological structures in prospecting operations for petroleum and other minerals. They have also been used for measuring the thickness of ice sheets covering polar regions (*see* INTERNATIONAL GEOPHYSICAL YEAR: *The Earth's Structure and Composition*).

Earthquake waves are propagated from the source in all directions throughout the earth and are affected or modified by the physical conditions occurring over their paths. Consequently study of their forms and the patterns of their occurrence over the earth as revealed by seismographs has been the principal source of knowledge concerning the nature of the earth's interior. The seismograph's contribution to geophysical and geological knowledge is thus comparable to the contributions of the telescope and microscope to astronomy and biology respectively.

(*See* also EARTHQUAKE; EARTHQUAKE. For their application in prospecting *see* GEOPHYSICAL PROSPECTING.)

General Types.—All seismographs fall into one or other of two general forms depending upon their initial responding element or mechanism which is either a pendulum or a device responsive to strain. The pendulum consists of a weight, called an inertia reactor, suspended or attached to the ground in such a way that it is free to oscillate. If displaced from its rest position it is acted upon by a force known as a restoring-force which tends to return it to its rest position and which is proportional to the displacement. The restoring-force may be provided by a spring or by gravity as in the gravity pendulum. The time for one complete oscillation of the pendulum is called the period of the pendulum. If the pendulum were well constructed and contained only a restoring-force, once set into oscillation it would continue to vibrate indefinitely and would thus be of little use in measuring ground movements.

Accordingly, an additional force is introduced into the system proportional negatively to the velocity of the pendulum and known as a damping force. The damping force is derived almost universally from reaction of electric currents generated in a moving conductor attached to the pendulum and immersed in the field of a magnet fastened to the supporting structure. The damping force is adjusted near or exactly to the critical value which allows the pendulum freely to just return to rest from a displaced position. When the ground vibrates, the inertia of the pendulum prevents it from moving identically with the ground and the difference in motion between the two is the quantity measured and recorded on the recorder, after suitable magnification and other modification. The written record is known as a seismogram.

In order fully to measure the ground movement, three perpendicularly oriented pendulums are required, one for the vertical or up and down component of motion and two for the horizontal components, usually oriented north-south and east-west. The simplest type of vertical component pendulum is represented by a weight suspended by a spring. With suitable transverse restraints, instruments of this type have found extensive use in prospecting seismology as well as in earthquake recording where such pendulums designed with periods of about 1 sec. are particularly well suited to the shorter period components of seismic waves ranging in period from about 0.2 sec. to 10 sec. Pendulums of this type are not constructed with periods much longer than 1 sec. because the extension of the spring by the weight of the inertia reactor is proportional to the square of the period and so becomes too large for practical use. In order to get around this difficulty Sir J. A. Ewing introduced (1880) a mechanical structure so arranged that a portion of the spring tension produces a negative restoring force; *i.e.*, a force which acts to drive the pendulum away from its rest position rather than toward it. Lucien LaCoste modified the original mechanical structure somewhat and introduced in addition a zero-length helical spring—one which when fully collapsed has a large built-in residual tension so that when extended just sufficiently to separate the coils, tension is exerted equal to that of an ordinary spring extended a distance equal to its own unextended length. The residual tension is due to the twist of the spring wire introduced during winding of the helix. The LaCoste pendulum is shown schematically in fig. 4A. With this form, periods up to 80 sec. have been attained with good stability.

The simplest horizontal component pendulum is perhaps the gravity pendulum such as used in pendulum clocks. Its use in seismographs has been limited, however, by a condition similar to that of the simple vertical component pendulum in that for periods much longer than 2 sec. the dimensions are impracticably large. A form in common use which gets around this difficulty is shown in fig. 4B. Here the inertia reactor consists of a weight attached to one end of a horizontal boom. The other end of the boom is pivoted against the vertical supporting column. The weight is supported by a wire fastened at the top of the column. If the weight is displaced horizontally a small distance, the boom rotates through a small horizontal angle and at the same time the geometry of the structure is such that the boom raises a slight amount. Gravity thus provides a restoring force which acts to return the boom to its rest position, and with careful design such pendulums can be made with periods extending to one minute or more. Another horizontal component form due to J. A. Anderson is known as the torsion pendulum (fig. 5). In this the inertia reactor is a small cylinder or vane supported eccentrically by a thin wire suspension. This type has found extensive use for periods from 0.1 sec. to 1 sec., although it can be constructed with longer periods.

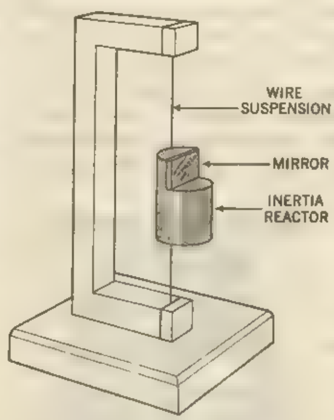

FIG. 5.—SCHEMATIC DIAGRAM OF TORSION PENDULUM

Recording Systems.—In the early seismographs movement of the pendulum was magnified and recorded on a strip of smoked paper using a system of levers ending in a pointed stylus. The useful magnification with these recorders was severely limited by the circumstance that any frictional or other force acting on the stylus tip is reflected back to the inertia reactor by a factor equal to the square of the magnification. To get around this difficulty John Milne and J. J. Shaw introduced a system using optical magnification with photographic recording. A small mirror was arranged to be rotated by a movement of the pendulum so that a beam of light reflected from the mirror produced a magnified replica of the motion of the pendulum on a strip of photographic paper wrapped around a slowly rotating drum. This system was brought to its ultimate efficiency in the torsion seismograph mentioned earlier. In this form the mirror is attached directly to the tiny inertia reactor, less than an eighth of an inch in diameter, so that a small linear movement of the ground produces a relatively large rotation of the inertia reactor and mirror. Magnifications of 3,000 times were attained with this instrument for short pendulum periods. For longer pendulum periods such direct coupled recording systems are severely limited as to useful magnification because of the horizontal pendulum's sensitivity to tilt of ground (varies as the square of the pendulum period) and because of creep and thermal response of the spring in vertical component pendulums.

Electromagnetic Seismographs.—To overcome this limitation B. B. Golitsyn developed an electrical system in which recording was accomplished photographically with a D'Arsonval galvanometer actuated by an electromagnetic transducer on the pendulum. The transducer takes the form of a coil of fine wire attached to the inertia reactor and arranged to move in the field of a strong permanent magnet fixed to the instrument. With movement of the pendulum the transducer thus becomes a small generator of electrical power which serves to actuate the recording galvanometer. Since the mirror system of the galvanometer was very small and of light weight in comparison with the pendulum weight of about 50 lb., the available magnification was increased to around 10,000 times. But of greater importance is the fact that the electromagnetic transducer output voltage depends upon the rate of movement of the coil relative to the field rather than the displacement. It thus produces negligible output for the slow movements of the pendulum caused by temperature

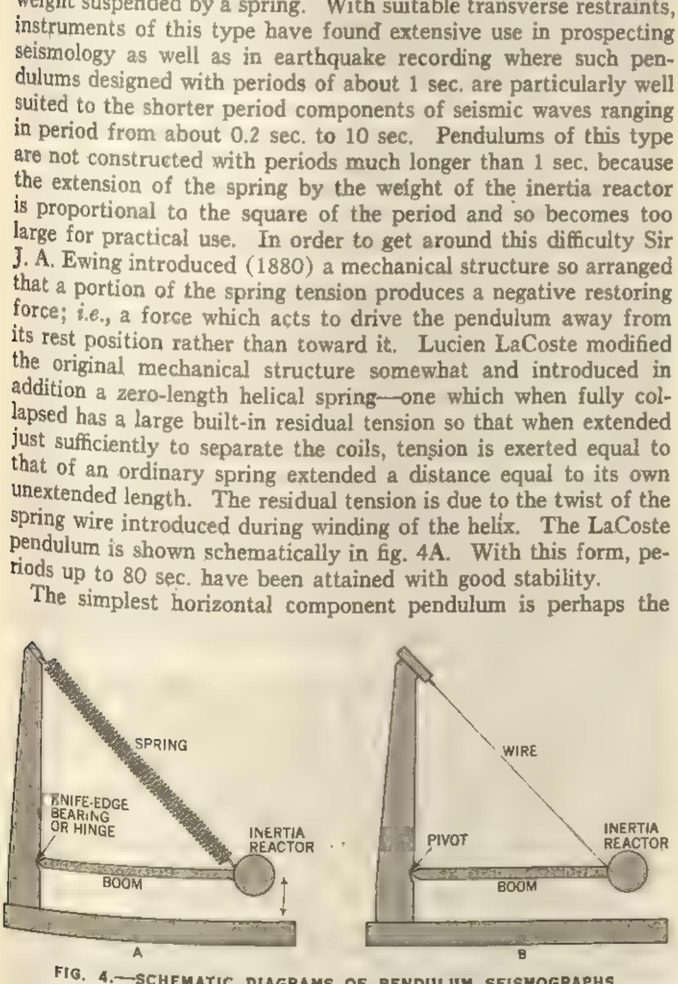

FIG. 4.—SCHEMATIC DIAGRAMS OF PENDULUM SEISMOGRAPHS
(A) LaCoste pendulum used to measure vertical component movement of the ground and (B) pendulum used to measure horizontal ground movement

changes or tilts of the ground and consequently higher magnifications for seismic movements can be used. Golitsyn adjusted his pendulum and galvanometer to the same period, about 12 to 15 sec. Later Frank Press and Maurice Ewing, and then Press, Ewing, and Francis Lehner made extensive modifications of the Golitsyn seismograph resulting in greatly improved performance, especially for very long period waves. They changed the vertical component pendulum to the LaCoste type and compensated it for barometric pressure variations which produce movements of the pendulum because of the accompanying changes in the buoyancy of the air on the inertia reactor.

In addition, they increased the pendulum period to about 30 sec. and the galvanometer period to 90 sec. Their instrument provides a maximum magnification of about 4,000 times in the period range from about 15 to 40 sec.

Another type of electromagnetic seismograph was developed by Hugo Benioff especially for recording the short period components of seismic waves in the range 0.2 to 5 sec. He used a cylinder of 200-lb. weight for the inertia reactor and suspended it directly by a helical spring (fig. 6), to give a free period of 1 sec. For such a large weight and short pendulum period it was impracticable at the time to use the Golitsyn type moving coil transducer because of the great size of the magnet required. He therefore used a variable reluctance magnetic transducer for providing the required electrical output. In this form magnetic flux from a permanent magnet flows across four air gaps formed between laminated iron alloy pole faces in a push-pull arrangement as shown in the drawing. Movement of the pendulum varies the length of one pair of gaps relative to the other with a resulting change in flux in the two circuits. These changes generate voltages in the two sets of coils wound around the laminated iron alloy armatures carrying the flux, and the induced currents operate two galvanometer recorders simultaneously with galvanometer periods of 0.2 sec. and 90 sec. respectively. The large weight of the inertia reactor and the high efficiency of the reluctance transducer allow maximum magnifications of about 1,000,000 times with the 0.2 sec. galvanometer for periods in the vicinity of 0.5 sec.

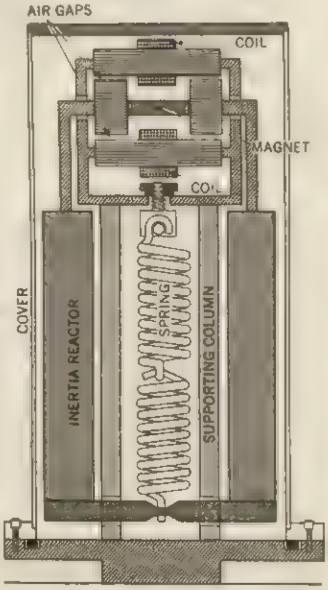

FIG. 6.—SCHEMATIC SECTION OF BENIOFF VERTICAL COMPONENT SEISMOGRAPH

Such high magnification can only be used in the few regions of the earth where the ground unrest is very small. For most regions the amplitudes of the ground unrest limit the useful magnification to 50,000 times or less. With the long period galvanometer the magnification is approximately 2,000 times at 1-sec. periods and gradually falls off to 30 times for periods of 90 sec. Because of a negative restoring-force introduced by the reluctance transducer, the spring and other constraints of this seismograph are much heavier than those of other types for the same pendulum periods. The instrument is thus extremely rugged relative to other seismographs.

Strain Seismograph.—The strain seismograph was developed by Benioff in 1935. Unlike pendulum seismographs which respond to vibration of the ground, the strain seismograph responds to linear strain (stretching or compression) of the ground. Strain is produced by seismic waves since in different parts of the wave the ground is displaced by different amounts or even in opposite directions. Thus during the passage of a seismic wave train past a given observing point, the ground is alternately compressed and stretched in conformity with the undulations of the wave. The strain produced by seismic waves is exceedingly small so that the measuring elements of the strain seismograph must be very sensitive. The principle of the strain seismograph is illustrated in fig. 7. The two piers, usually made of 12-in. steel pipe, are sunk into rock. A length standard in the form of a tube of fused quartz 60 to 100 ft. long is firmly attached to one pier and extends to within a short distance of the other pier. When the ground between the piers is stretched or compressed during passage of a seismic wave, the distance between the piers changes and this in turn alters the separation between the end of the standard tube and the adjacent pier. With a proper transducer and recorder this small change in separation can be magnified and recorded. Benioff uses two types of transducers. One is the variable reluctance electromagnetic type similar to the one described in the preceding paragraphs for his pendulum instrument. With this transducer, recording is accomplished with a galvanometer on photographic paper. The other transducer is a carrier-current resonant capacitance bridge type recording with an ink-writing galvanometer on a paper strip. Although the operation of this type of transducer is too highly technical to be described here, it is simple and stable in practice and records not only strains produced by seismic waves but also the strains produced in the solid earth by the tidal forces of the sun and moon. As to be expected, the response characteristics of the strain seismograph differ from those of pendulum instruments in a number of ways including different directional and period characteristics, and absence of response to tilt of the ground. (Hu. B.)

SEISTAN (SISTAN), an extensive border region of eastern Iran and southwestern Afghanistan, centred on the Hamun-e Saberi about latitude 31° 30′ N and longitude 61° E. Its area is roughly 10,000 sq.mi. (28,000 sq.km.) of which about 40% is in Iran. The total population is approximately 300,000, of whom about half reside in Iran.

Physically, Seistan is a large depression at a general level of 1,500–1,700 ft. (450–520 m.) which receives the drainage of Harut Rud (Adraskan) and Farah Rud from the north, Khuspas Rud and Khash Rud from the east, Helmand (*q.v.*) River from the south, and the Rud-e Bandan and Shur Rud from the west. Of these only the Helmand has a permanent flow. These rivers fill a series of lagoons called *hamun* (*e.g.*, Hamun-e Saberi, Hamun-e Puzak) and in high flood inundate the extensive reed tracts (*naizar*) south of the lagoons, thus forming a great shallow lake which discharges its redundant waters through the Shelagh Channel into another southerly depression called Gaud-e-Zirreh. Three large deltas intruding into this lagoonal area form the main regions of settlement: Lash-Juwain on the Farah Rud, Chakhansur on the Khash Rud (both in Afghanistan), and Seistan proper on the Helmand River (see *History*, below).

Seistan has a true desert climate with a highly irregular rainfall averaging less than 4 in. (100 mm.), extreme heat in summer, and frost spells in winter. A special plague is the "wind of 120 days," which blows unceasingly from the north during summer, causing much erosion and the shifting of sand dunes.

The population is chiefly Tajik (*see* TADZHIK), though of mixed descent as many alien groups have more or less amalgamated with the original Iranian stock. There is a strong nomadic element of Balochi and Brahui, besides groups of Jat and Gujars, and Gawdars who breed strong, black, humped cattle.

Incessant internal strife and corrupt administration, together with its isolation, helped to keep Seistan's economic standard low. Irrigation was formerly practised by yearly rebuilding a dam (Band-e-Seistan) on the Helmand near where it enters Iranian

Seistan. The dam was annually swept away by flood. In 1952–53 two barrages, Kuhak and Zahak, were constructed to irrigate approximately 320,000 ac. (130,000 ha.) of land. The chief crops are wheat and barley with a little cotton and maize (corn).

In 1959 Iranian Seistan was united with Baluchistan (*q.v.*) to form an *ostan* (province). The only town of importance in Iranian Seistan is Zabol (pop. [1956] 12,221), the seat of the governor when Seistan and Qayen formerly together constituted a hereditary governorship. A motorable road (70 mi.) from Zabol links with the Meshed-Zahedan highway, and Zahedan with its railhead to Quetta is the international outlet. Chakhansur, 35 mi. (56 km.) E of Zabol, is the chief town of Afghan Seistan. (H. Bo.)

History.—Called Zranka in Darius I's inscriptions and Drangiana by Strabo, the country now known as Seistan is the reputed land of origin of the legendary Kayanian dynasty of Persia. After forming part of the Achaemenid Empire, Seistan was successively under Seleucid and Bactrian Greek control. Occupied by the Sakas, a Scythian tribe, *c.* 155 B.C., the country became known as Sakastan. The Sakas were later ousted by the Parthians, but their control over the country was often nominal.

In A.D. 226 the Sasanian Persians under Ardashir I conquered Seistan. The Sasanian monarchs did much to develop agriculture by constructing dams and irrigation canals. They introduced rule by satrap, often leaving control in the hands of members of the Kayanian family whose descendants still live in Seistan. In the reign of Khosrau I, the capital of Seistan was Zaranj, the site of which (now called Nad-i-'Ali) is 22 mi. E of the modern town of Zabol. The Zoroastrian religion flourished under the Sasanians.

In the mid-7th century A.D. the Muslim Arabs invaded Seistan and introduced Islam, but the fluctuating measure of control exercised by the caliphate probably enabled Zoroastrianism to survive longer there than in other parts of the country. In the latter part of the 9th century a Seistani named Yaqub ibn al-Layth al-Saffar ("the coppersmith") founded the Saffarid dynasty in Seistan. Yaqub and his brother and successor, Amr, extended their sway over the greater part of Persia. After the downfall of the Saffarids, Seistan became part of the empire of the Samanids. It was probably at this time that a new capital called Zahedan, 6 mi. SW of Zaranj, was founded. In 1003 Mahmud of Ghazni wrested Seistan from the Samanids, but under both the Samanids and the Ghaznavids the inhabitants retained some measure of governmental control through their own *maliks* (kings) of the Kayanian line.

Seistan twice suffered greatly at the hands of the Mongols in the 13th century. In 1363 Timur (Tamerlane) invaded Seistan. His rule was mild. After a revolt, however, he invaded Seistan again, in 1383, taking a terrible vengeance. He destroyed Zahedan and other cities and also the great dam over the Helmand River. In 1407–08, after a further revolt by the Seistanis, Shahrukh, Timur's son and successor, wrought further havoc to the dams and the canal system.

Seistan subsequently was independent under its own *maliks*. Although Shah Ismail I of Persia conquered Seistan, he and his successors left the *maliks* largely in control. In 1722 a *malik* Mahmud Seistani made himself sovereign over Seistan and much of Khurasan, but he was defeated and put to death by Nadr Quli Beg, the future Nadir Shah. In 1747 Seistan came under the control of the Afghan, Ahmad Shah Durrani, and after his death it was for long a bone of contention between Herat and Kandahar, but in 1865 Nasir ad-Din Shah of Persia took possession of it. Complications later ensued between Persia and Afghanistan which led to British arbitration and the delimitation of the Perso-Afghan frontier by the Seistan Commission under Sir Frederick J. Goldsmid in 1872. In accordance with the arbitration award, Persia handed over to Afghanistan the part of Seistan situated on the right bank of the Helmand River. The work of delimitation was finally brought to a close by the McMahon Mission in 1903–05. (L. Lo.)

SEJANUS, LUCIUS AELIUS (d. A.D. 31), close adviser of the Roman emperor Tiberius, was a son of Seius Strabo, a Roman knight from Etruria, and on his mother's side was related to the Cornelii Lentuli, a distinguished senatorial family. He was adopted by an Aelius, possibly Aelius Gallus who was prefect of Egypt. He accompanied Gaius Caesar, Augustus' grandson, to the East in A.D. 1; and in 14, directly after Tiberius' accession, was made his father's colleague as prefect of the Praetorian Guard, becoming sole prefect a year or two later. He concentrated his cohorts in a single camp, the Castra Praetoria, under the Viminal Hill just outside the walls of Rome. After the death in 23 of Drusus Caesar (*q.v.*), whom Sejanus was later accused of having murdered, he systematically attacked the party of Agrippina ("the Elder"; *q.v.*), whose sons were then Tiberius' probable heirs. In 25 Tiberius refused him permission to marry Livilla, Drusus' widow, but his power grew when next year he persuaded Tiberius to retire to Capreae (Capri), and in 29 he succeeded in having Agrippina and her son Nero exiled. In 31 Sejanus, hitherto not even a senator, became consul, and Tiberius was holding out hopes that he would be granted tribunician power. But suddenly the emperor, apparently warned by his sister-in-law Antonia, became suspicious of Sejanus' designs, and by a series of maneuvers had him arrested and executed on Oct. 18, afterward taking terrible vengeance on his party. The extent of Sejanus' plotting is a mystery, but it is not impossible that he planned to murder Tiberius and become emperor forthwith.

SEKONDI-TAKORADI, a seaport of Ghana, Africa, and a city from 1963, was formed of the old town and surf port of Sekondi and the modern deep-water port of Takoradi, opened in 1928. Pop. (1960) 123,313. Sekondi is a mixture of old and new buildings on a hilly site. Takoradi is planned as a modern town; in the harbour area is High Street with government and commercial offices and large stores, and there are estates for the workers shaded by nim trees, and a modern hospital. Two breakwaters enclose 220 ac. (90 ha.) of water area, with six quay berths, including one used only for manganese export, and moorings for several vessels. On the seaward side of the lee breakwater are berths for the loading of bauxite and the discharge of oil. The harbour is the terminus of the western branch of Ghana Railways, and motor roads link the city with the coast and the interior. The airport constructed during World War II is served by internal and external airlines. There are local light industries including timber and cocoa butter mills, railway repair shops, fishing-boat building, and cigarette making. The local inhabitants are peasant farmers or small fishermen, and market and street retail trade is conducted by women.

Nothing remains of Witsen Fort built at Takoradi by the Swedes in 1652–54. The Dutch and British both built forts at Sekondi in the 17th century which were destroyed in the 1690s by the Ahanta tribes, who inhabit the district. The Dutch rebuilt Fort Orange, which was bought by the British in 1872. It is the only surviving fort in the city and is used as a lighthouse. The rebuilt British fort passed to the French in 1779, was ceded to the Dutch in 1867, and bought back by the British in 1872, but has subsequently become a ruin. (E. A.-HA.)

SELANGOR, a state of the Malaysia federation and a constitutional sultanate, on the Strait of Malacca, bounded N by Perak, E by Pahang, and SE by Negri Sembilan. It is the second largest of the states of Malaya in population (1,012,929 in 1957) and the seventh in area (3,167 sq.mi. [8,203 sq.km.]). It consists of part of the western coastal plain, reaching inland to a mountainous limit along the central range which provides a natural boundary with Pahang. The Bernam River separates the state from Perak, and low hills form a southern divide from Negri

Sembilan. The history and economic development of the state have been closely bound up with the short Klang River, which has large mangrove-covered islands on its deltaic fringe. Along this river and the nearby Langat River the waterborne Malays who founded the state settled, as did the immigrants who pioneered the economy of the country. The foothill zone around the river near Kuala Lumpur (*q.v.*), the capital of the Malaysia federation and of Selangor, is Malaya's second largest tin-producing region. There, too, the tin is alluvial, the ore occurring as black, sandy grains deposited by streams debouching from steep courses in the hills which include Triassic limestones. The low-lying surface has been repeatedly turned over by gravel pump mines and dredges, drastically modifying the drainage pattern, diverting the Klang at many places, and hastening coastal sedimentation.

During the 18th century Selangor became an independent state ruled by Bugis from Makasar in the Celebes. In the late 19th century Chinese tin miners, mainly from Singapore, arrived in the state and civil war in their jungle camps led to British intervention, culminating in the establishment of protectorate status for Selangor in 1874. In 1895 Selangor joined the Federated Malay States. Occupied by the Japanese during 1942–45, after World War II it became part of the Federation of Malaya and subsequently of the Malaysia federation. (*See* MALAYSIA.)

At the 1957 census the Chinese formed 48% and the Indians 20% of the state's population, together outnumbering the Malays (29%), although Selangor has been the focus of Malay nationalist politics. The population of Kuala Lumpur was 316,230 (mun.). During 1947–50 there was a large-scale resettlement of urban and rural refugees, and 18 new villages were created (pop. [1957] about 43,000, mainly Chinese). According to the 1957 census about two-thirds of the state's population lived in about 40 towns.

The legislature consists of the sultan and the state legislative assembly. The ruler appoints an executive council, whose members must also be members of the legislative assembly. He acts on the council's advice except in certain matters. The legislature's responsibilities include land tenure and local government.

Selangor has a broad-based economy, its tin mining, which yields about 20% of the national output, being supplemented by about 46,000 ac. of paddy and about 410,000 ac. of rubber, a third of the last named in small holdings. Other agricultural crops include pineapples and palm products.

In 1890 a short railway was built between Kuala Lumpur and Klang, about 18 mi. away, as the river proved inadequate for the transport of goods. From this grew the rail and road links south to Singapore and north to Penang which handled the increasing output of rubber and tin while Klang declined as mining inland disturbed the river profile. Between World Wars I and II the Malayan railway embarked on developing Port Swettenham (now Malaya's second port), beside a broad channel on the delta below Klang, to handle bulky commodities. In the early 1960s the total net registered tonnage of ships entering Port Swettenham in cargo was about 6,100,000 or about 40% of the total for Malayan ports. (E. H. G. D.)

SELBORNE, ROUNDELL PALMER, 1ST EARL OF (1812–1895), English lawyer and statesman who was responsible for the passage of the Judicature Act of 1873, was born at Mixbury, Oxfordshire, on Nov. 27, 1812; his father was rector of the parish. Educated at Rugby and Winchester, and at Trinity College, Oxford, he was called to the bar on June 7, 1837, and soon had a good chancery practice. He wrote for *The Times* and the *British Critic*, and took an active interest in church affairs.

In 1847, and again in 1853, Palmer was returned as member of Parliament for Plymouth, as a Peelite, and in the House of Commons took an active and—in relation to the Crimean War, the Second Opium War with China, and religious questions—an independent part. This attitude was disapproved of by his constituency, and he gave up his seat at the election of 1857. In 1848 he married Lady Laura Waldegrave, and in 1849 became a queen's counsel. In July 1861 he accepted from Lord Palmerston the office of solicitor general, a knighthood, and a safe seat for the borough of Richmond in Yorkshire; in September 1863 he became attorney general and, as such, was adviser of the ministry, in the courts and in the House, on the questions which arose out of the American Civil War. In 1866 he advocated making household suffrage the basis of representation, an expression of opinion which probably influenced the Reform Bill of the following year—in the discussions on which Palmer took a prominent part, and especially in opposition to the so-called "fancy franchises" originally proposed by its authors. In April 1868 he refused to support Gladstone's measures for the disestablishment of the Irish Church, and after the election of that year he declined Gladstone's offer of the office of lord chancellor.

The Treaty of Washington cast a great duty upon Palmer. After the conclusion of the American Civil War very large claims were preferred against Great Britain for alleged breaches of her duty as a neutral power; and after long negotiations Great Britain and the United States agreed to arbitration.

In September 1872 Gladstone again offered him the great seal and he accepted it, with the title of Lord Selborne. In the following year Lord Selborne carried through parliament the Judicature Act, which produced a fundamental change in the judicature system. By the operation of the act one supreme court with several divisions was constituted; each division could administer the whole law; the conflict of divergent systems of law was largely overcome by declaring that, when they were at variance, the principles of equity should prevail over the doctrines of the common law. The details of this great change were embodied in a code of general rules prepared by a committee of judges, over which Lord Selborne presided week by week for two years. "If," he wrote in his memoirs, speaking of the act of 1873, "I leave any monument behind me which will bear the test of time, it may be this." This unification of the courts was more or less contemporary with the construction of a single building to house them; in 1882 Queen Victoria personally presided in the new law courts and handed them over formally to Lord Selborne. On this occasion he received an earldom. In 1885 he definitely broke with Gladstone over Home Rule and disestablishment. But though he never held office again, he continued to sit in the House of Lords both to hear appeals and for ordinary business.

In 1886 Lord Selborne published *A Defence of the Church of England* and in 1888 *Ancient Facts and Fallacies Concerning Churches and Tithes*. He died on May 4, 1895, at his seat in Hampshire after an attack of influenza.

See his *Memorials*, ed. by Lady Sophia Palmer, 4 vol. (1896–98)

SELBORNE, WILLIAM WALDEGRAVE PALMER, 2ND EARL OF (1859–1942), British statesman and high commissioner for South Africa (1905–10), was born in London on Oct. 17, 1859, the son of Roundell Palmer, who was created 1st earl of Selborne in 1882. Educated at Winchester and University College, Oxford, he took a first class honours degree in modern history. In 1883, when he was Viscount Wolmer as his father's heir he married Lady Beatrix Maud Cecil, eldest daughter of the 3rd marquess of Salisbury. He was M.P. for East Hampshire from 1885 to 1892 and for West Edinburgh from 1892 until 1895 when his father's death took him reluctantly to the Lords. Like his father he was a Liberal Unionist; and from 1895 to 1900 he was undersecretary to Joseph Chamberlain at the colonial office.

He entered his father-in-law's cabinet as first lord of the admiralty in 1900. He brought back Adm. Sir John (later Baron) Fisher to the board of admiralty in 1902, and with him revolutionized both the Navy's training system and its capital ships, turning it from an obsolescent force into the most powerful fleet in the world. The completion of this revolution, with the launching of the battleship "Dreadnought," came after Selborne had succeeded Lord Milner as high commissioner for South Africa and governor of the Transvaal and Orange River Colony in May 1905. When the Liberal government took office (December 1905), it decided to give both colonies self-government without delay. Selborne loyally accepted the new situation and in his memorandum of January 1907 proposed that the two colonies should unite with Natal and the Cape Colony to form the Union of South Africa; this policy was accepted. He returned to England in May 1910 just before the South Africa Act, establishing the union, came into force.

He then became one of the leading "die-hards" who opposed the Parliament Bill (*see* ENGLISH HISTORY: *The 20th Century: Struggle With the House of Lords*). During World War I he again cooperated with the Liberals, becoming president of the board of agriculture in the first war coalition of May 1915; but he resigned in June 1916 in protest at the compromise policy that H. H. Asquith pursued in Ireland after the Easter Rising in Dublin. Mistrusting Lloyd George, he refused to join his ministry in December 1916 and also rejected his subsequent offers of the viceroyalties of India or Ireland or of a marquessate. After 1918 he devoted himself partly to the affairs of the Church of England and partly to unsuccessful attempts to reform the House of Lords. Selborne died in London on Feb. 26, 1942. (M. R. D. F.)

SELBORNE, a village 5 mi. (8 km.) S of Alton, Hampshire, Eng., is celebrated for its associations with the naturalist Gilbert White (*q.v.*), who wrote his classic *Natural History and Antiquities of Selborne* (1789) while curate there. His house, "The Wakes," is open to the public and his grave is in the churchyard. The restored church contains interesting medieval work. At Priory Farm, about 1 mi. NE of the village, are the scanty remains of a medieval house of Augustinian canons. The National Trust owns Selborne Hill (241 ac. of common and freehold land) and the Long and Short Lythes (16½ ac., mostly hanging beech woods). Pop. (1961) 1,034. (A. G. G.)

SELDEN, JOHN (1584–1654), English jurist, legal antiquary, and Oriental scholar, was the acknowledged master of the Antiquarian Society, the centre of English historical research in the 17th century. He was born on Dec. 16, 1584, at Salvington, Sussex. His father, also John Selden, held a small farm. Selden was educated at Chichester grammar school and Hart Hall, Oxford. In 1603 he entered Clifford's Inn, London, and in 1604 migrated to the Inner Temple; in 1612 he was called to the bar. His practice was mostly conveyancing, and he rarely went into court.

Selden's early works were: *England's Epinomis* and *Jani Anglorum facies altera* (1610), which deal with the progress of English law down to Henry II; *Titles of Honour* (1614), which, in spite of some obvious defects and omissions, has remained to the present day the most comprehensive and trustworthy work of its kind; *Analecton Anglo-Britannicon* (1615); and *De diis Syriis* (1617), which immediately established his fame as an oriental scholar. For his *History of Tithes* (1618), Selden was summoned before the Privy Council and compelled to retract his opinions, or at any rate what were held to be his opinions. Moreover, his work was suppressed and he himself forbidden to reply to any of the controversialists who had come or might come forward to answer it.

He was first elected to Parliament in 1623. Even before his election he had shown his political sympathies by assisting in the preparation of the memorable protestation on the rights and privileges of the House of Commons affirmed by the House in 1621. For this he had been committed to the Tower of London. After his election he took a prominent part in the impeachment of the duke of Buckingham, was counsel for Sir Edmund Hampden in the "benevolence" case of 1627, and had a large share in drawing up and carrying the Petition of Right (*q.v.*).

In the session of 1629 Selden was one of the members mainly responsible for the tumultuous passage in the House of Commons of the resolution against the illegal levy of tonnage and poundage, and, along with Sir John Eliot, Denzil Holles, Benjamin Valentine, William Strode, and the rest, he was sent once more to the Tower. He was released by the intervention of Archbishop Laud. In 1628, at the suggestion of Sir Robert Cotton, he had compiled, with the assistance of Patrick Young and Richard James, a catalogue of the Arundel marbles. About this period he seems to have inclined toward the court rather than the popular party, and even to have secured the personal favour of the king. To him in 1635 Selden dedicated his *Mare clausum*, against the freedom of the sea, and under the royal patronage it was put forth as a kind of state paper. It had been written 16 or 17 years before but James I had prohibited its publication for political reasons; hence, it appeared a quarter of a century after Grotius' *Mare liberum*, to which it was intended to be a rejoinder. He was returned to the Long Parliament without opposition for the University of Oxford.

Selden joined in the protestation of the Commons for the maintenance of the Protestant religion according to the doctrines of the Church of England, the authority of the Crown and the liberty of the subject. In 1643 he participated in the discussions of the assembly of divines at Westminster and was appointed shortly afterward keeper of the rolls and records in the Tower. In 1646 he subscribed the Solemn League and Covenant and in 1647 was voted £5,000 by Parliament as compensation for his sufferings under the monarchy. He published in 1642 *Privileges of the Baronage of England when they sit in Parliament* and *Discourse concerning the Rights and Privileges of the Subject;* in 1644 *Dissertatio de anno civili et calendario reipublicae Judaicae;* in 1646 his treatise on marriage and divorce among the Jews entitled *Uxor Ebraica;* and in 1647 the earliest printed edition of the old English lawbook *Fleta.* In 1650 the first part of *De synedriis et prefecturis iuridicis veterum Ebraeorum* appeared, the second and third parts in 1653 and 1655, and in 1652 Selden wrote a preface and collated some of the manuscripts for Sir Roger Twysden's *Historiae anglicanae scriptores decem.* After the death of the earl of Kent in 1639 Selden lived with his widow. It is believed that they were married, although the marriage does not seem to have ever been publicly acknowledged. He died at Friary House in Whitefriars on Nov. 30, 1654, and was buried in the Temple Church, London. Of all the members of the Antiquarian Society, Selden was the acknowledged master.

SELECTION, in biology, is that process whereby individuals with certain genetic endowments are chosen from a population of animals or plants apparently because they are more suited than others to a given environment. These "fitter" individuals are favoured by Nature and are selected from the widely variable pool of all genetic endowments produced. They survive and multiply more successfully than the others, and accordingly become more numerous with each succeeding generation, as long as the environment remains stable. This culling of fitter types, called natural selection, is believed by most biologists to have been the chief impelling and directing agent of organic evolution on earth.

When man began to choose one kind of animal or plant over another, either consciously (as in husbandry and horticulture) or unconsciously (as in extermination of unwanted forms like weeds and predators), he superimposed another selective influence on nature: this kind of interference is called artificial selection.

A third, strongly felt selective pressure is exerted through the attraction of one sex for the other. Simply stated, sexual selection means that among many species there is a constant preference for mates that are strongest, handsomest, most colourful, or attractive in any number of ways that are assumed to provide sexual stimulation, eventual mating, and ultimate continuation of those qualities in offspring.

NATURAL SELECTION

History.—Some historians profess to see the concept of natural selection adumbrated in the creation myths of Empedocles (5th century B.C.) and Lucretius (1st century B.C.), who believed that body parts appeared in the world before complete bodies, that these parts proceeded to combine at random, and that only viable combinations survived. P. L. M. de Maupertuis in 1745, J. C. Prichard in 1813, W. C. Wells in 1813, and especially Edward Blyth in 1835–1837, all expressed ideas implying processes that would be described at present as natural selection. But only Charles R. Darwin and Alfred Russel Wallace (*qq.v.*) in 1858, and especially Darwin in 1859, formulated a theory of evolution by natural selection. Both Darwin and Wallace credited their reading of Malthus' *Essay on the Principle of Population* (1798) as having suggested natural selection to them.

Malthus (*q.v.*) argued that human populations tend to grow in geometric progression, while their food supply increases only

arithmetically; and that more children are born than grow to maturity, because the rest are eliminated by hunger, disease, and war. Darwin and Wallace saw that the argument applies to all living species; they also perceived a similarity between the Malthusian elimination of the surplus population and artificial selection, whereby agriculturists and fanciers select for reproduction those individuals that possess the qualities considered useful or interesting by the breeders. In nature, the survivors in the "struggle for existence" are also likely to carry somewhat different genetic endowments (genotypes) from those who do not survive. Consequently, the genotypes of the succeeding generations will be different from those of the preceding ones, and the difference will usually be in the direction of a greater fitness of the descendants in the environments in which the species lives.

Meaning of Fitness.—Emotionally loaded metaphors, such as "struggle for existence," "survival of the fittest," "eat or be eaten," etc., were used by the early Darwinists, sometimes rather carelessly. This opened the way for misuse of the theory of natural selection as a pseudoscientific justification of war, exploitation, and cruelty. But who is the fittest? The strongest? The most aggressive? P. A. Kropotkin (1902) correctly pointed out that survival and biological success are promoted by cooperation at least as often as by combat.

The modern concept of natural selection overcomes these difficulties. The Darwinian fitness, adaptive value, or selective value (these terms are synonyms) of a genotype is measured merely in terms of its reproductive efficiency. Bodily vigour, strength, combativeness, or cooperativeness, etc., are not in themselves reliable measures of Darwinian fitness: they contribute to, or detract from, fitness only insofar as they influence the reproductive success of a genetic constitution. The adaptive value of a genotype is the mean contribution of its carriers, relative to those of other genotypes, to the gene pool of the succeeding generation.

Some examples will make the concept of Darwinian fitness clear. Mules are no less vigorous than their parents, horses and donkeys, under many conditions. Yet the selective value of a mule is zero, since mules are completely sterile and their genes are not perpetuated. By contrast, hereditary diseases that afflict their victims after the close of the reproductive period (diseases of old age) do not directly diminish Darwinian fitness, if children are born before the onset of the disease. In the house mouse, certain genes are favoured by natural selection because they are passed to more than 50% of the progeny of the heterozygous males, despite the fact that these genes are lethal in homozygous condition (*i.e.*, in a double dose).

How Selection Operates.—The evolution of man, like that of any other biological species, was governed in the past by natural selection acting upon natural variation (*see* VARIATION). Some writers have claimed that in modern mankind natural selection has been relaxed or even removed altogether. This claim is, at least in part, based on a misunderstanding. Natural selection is not necessarily selection taking place in nature untouched by human activities. No matter under what conditions our remote ancestors may have lived, the environments in which people live at present are largely those created by human culture. Even if these environments be regarded as unnatural, natural selection may operate to maintain or improve the adaptedness of our species for living in human societies with various forms and degrees of cultural development. Only if all existing human genotypes produced numbers of surviving children in exact proportions to their frequencies in the populations could selection be said to have been removed. This obviously is not the case. The inhabitants of different parts of the world have different reproductive rates, and everywhere some people die childless or have fewer children than do others.

In man as in all other organisms, the Darwinian fitness of different genotypes changes with time and varies in different places. Fitness is clearly a function of the environment. Certain bacteria are killed when placed on culture media containing the antibiotic streptomycin, except for carriers of a variant genotype, which are resistant to the drug. Moreover, some of the resistant variants die on media *without* streptomycin, because they "perversely" require this substance for growth. Obviously the fitness of the normal and the resistant genotypes in these bacteria depends upon the presence or absence of streptomycin in the environment.

Natural selection operates at present to perpetuate human genotypes that enable their carriers to live and reproduce in the environment created by man's culture and technology. Some of the genotypes that survive in these environments might have been incapacitating in our prehuman ancestors, and vice versa. This means that natural selection can enhance the adaptive value of the organism only in the environments that exist here and now; it has no prescience of the future. Natural selection is as incapable at present of maintaining the adaptedness of man to the conditions of the Stone Age as it is of preparing him for the conditions of the Atomic Age. In short, natural selection may be said to be thoroughly opportunistic.

The fact that natural selection continues to operate does not necessarily mean that all will be well with the human species in the future. A species may become too specialized to live in environments that may prove to be temporary, and may become extinct when the environments change (the rather sudden passing of the dinosaurs is a dramatic example). Furthermore, Darwinian fitness should not be equated with excellence in human estimation. It is not only possible but indeed probable that man will have to take the direction of his evolution in his own hands, and to replace natural by artificial selection.

Genetic Basis of Selection.—A gene may exist in more than one form, spoken of as alleles. Given allele *A* and allele *a* (in which *A* is dominant to *a*), a hybrid individual, or heterozygote (having received an *A* from one parent and an *a* from the other), will display only the character represented by *A*, that represented by *a* being masked and called recessive. There often exists a selection pressure favouring one allele over another. This pressure may be slight or intense. Selection will operate to preserve both alleles in the population, and tend to establish an equilibrium —even if one of the homozygous conditions (represented by *AA* and *aa*) bestows serious disadvantages upon the individual. Thus natural selection may operate to preserve in a population hereditary diseases or malformations, provided that the alleles that produce them in homozygotes confer hybrid vigour on the heterozygotes (*see* GENETICS: *Deleterious Genes in a Population*). The intensities of natural selection involved in the maintenance of some of these heterotic situations in nature are very large, and offer favourable opportunities for investigation of selection phenomena. The mathematical representation of natural selection is discussed in detail in GENETICS OF POPULATIONS; *see* also EVOLUTION, ORGANIC: *Statistical Transformation of Populations.*

ARTIFICIAL SELECTION

In contrast to natural selection, artificial selection is a purposeful process. The animal or plant breeder chooses some individuals to be the progenitors of the next generation, and limits or prevents the reproduction of others; in this way, breeders direct changes in the genetic composition of a population. The techniques of artificial selection were evolved by centuries of trial and error, and have been highly effective in developing domesticated animals and cultivated plants in accord with human needs and desires. With the progress of genetics the art became a scientific technique.

For any kind of selection to be effective, the individuals who leave relatively greater numbers of surviving progeny must be genetically different from those who do not. In other words, there must be some genetic variance in the traits selected. This was established in 1909 by W. Johannsen, who carried out experiments on selection for large and small seed size in beans. Selection was effective only when applied to a mixture of different genetic constitutions. It was without effect when applied to a pure line, *i.e.*, to progeny obtained by self-pollination of single individuals in a series of generations. Individuals that belong to a pure line are genetically identical, and any observable (phenotypic) differences between them are due to their having grown in varying environments.

One of the classical, and still widely used, methods of ensuring

a supply of genetic variance is hybridization (*see* HYBRIDISM). Many of the successful varieties and breeds of agricultural plants and animals have been obtained by selection within progenies of hybrids between two or more parental varieties. The parental varieties crossed often come from different countries and some of them may be initially quite remote from the ideal type that the breeder wishes to obtain. They may, nevertheless, supply the genetic building blocks from which selection may construct superior new genetic endowments. Such genetic building blocks can be obtained by using agents that cause mutations (*q.v.*), especially X-rays and other ionizing radiations.

See ANIMAL BREEDING; PLANT BREEDING. For a discussion of the artificial selection of human traits, *see* EUGENICS.

SEXUAL SELECTION

Females and males in many species of animals are more or less different in body size, coloration, or in the presence of various secondary sexual characters, such as beards in human males or enlarged breasts in human females. Darwin suggested that such differences evolved because the possessors of certain characteristics were generally more successful in mating or were usually more fertile than those with other characteristics. (*See* COLORATION, BIOLOGICAL: *Animal Colours: Function.*)

The range of applicability of the theory of sexual selection is rather uncertain. It is most plausible when applied to polygamous species, such as some monkeys or deer, in which the largest and strongest males may collect harems of numerous females, while weaker males are at least temporarily excluded from reproduction. The theory fares less well with monogamous species, in which fixed pairs are established for life or at least for a season. With males and females being about equally numerous, almost all individuals in such species find mates and consequently have a chance to reproduce. Secondary sexual traits may still be selected in monogamous species, if these traits enable their possessors to survive more often or to produce more offspring. (However, this is natural selection, rather than sexual selection as originally defined.)

A form of the theory of sexual selection may perhaps be used to explain the development of species signals and recognition marks. Several closely related species of animals often live in the same territory. And, hybridization of members of distinct species often results in production of poorly viable or sterile progeny. It is, therefore, advantageous for these species to develop characteristics that reduce the frequency of the "mistakes," and confine mating to individuals of the same species. Species differences in courtship rituals, and in the appearance, behaviour, and odours of the two sexes may well have arisen by way of sexual selection.

See COURTSHIP, ANIMAL; SEXUAL BEHAVIOUR: *Sexual Behaviour and Evolution; see* also references under "Selection" in the Index.

SELENE, the Greek word for the moon, was personified in ancient Greece as the moon goddess. She had no important cults or temples but was worshiped to a minor extent at the new and full moon. In genealogy her parents were the Titans Hyperion and Theia, her brother was Helios (sometimes alternatively called her father), her sister Eos (Dawn), her husband Zeus, and her daughter Pandia. By the 5th century B.C. Selene was sometimes identified with Artemis. One of the few legends in which Selene appears tells how she was wooed by Pan, who enticed her with a white fleece. The best known legend concerns her love for Endymion (*q.v.*). In art she was usually represented as a woman with the moon (often in crescent form) on her head driving a two-horse chariot (as on the lost statue from the east pediment of the Parthenon in Athens). Selene was called Luna in Latin; she had temples in Rome on the Aventine and Palatine hills.

See Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft*, 2nd series, vol. 2, col. 1136–44 (1921). (H. W. PA.)

SELENGA-ORHON RIVER SYSTEM consists of the Selenga River (Mongolian Selenge Gol) formed by the junction of the Ideriyn (Iderüin) and Mörön rivers, which rise in the Mongolian People's Republic (Outer Mongolia) south of Lake Hövsgöl (Höbsogöl), and the Orhon River (Mongolian Orhon Gol), which rises farther south at about latitude 47° N on the slopes of the Hangai Range. Both rivers flow in a northeasterly direction to join at Sühbaatar (Sühebaatar); the river, from that point called the Selenga, continues north into the Russian Soviet Federated Socialist Republic, U.S.S.R., and bends eastward to Ulan-Ude, the capital of the Buryat Autonomous Soviet Socialist Republic; from there it continues north to Tataurovo, where it swings abruptly westward and flows on into Lake Baikal. From Sühbaatar to its delta the Selenga flows down a gently graded slope giving access from Outer Mongolia to the plains of Asiatic Russia. The Trans-Siberian Railway follows the valley upstream to Ulan-Ude; from there a branch continues to Sühbaatar, then follows the Orhon and the Haraa (Hara) Gol to Ulan Bator, capital of the Mongolian People's Republic, from where it extends southeast to Peking.

The Selenga is 620 mi. (1,000 km.) long and is navigable from its mouth to beyond Sühbaatar. Its basin covers an area of 172,600 sq.mi. (447,000 sq.km.), and its width varies from an average 20–50 yd. (18–45 m.) to 70–170 yd. (64–155 m.) at high water; it is fed mainly by the summer rains. High water is 6–12 ft. (2–4 m.) above normal level, and the absolute variation is 9 to 18 ft. (3–5 m.). The river freezes over from the first half of November until the end of April. The annual flow is estimated at 7 cu.mi. The main tributaries in the Mongolian People's Republic are, on the right, the Orhon and Hanuy (Hanuyn) Gol; on the left, the Egiyn (Egiin) Gol. The main ones in the U.S.S.R. are, on the right, the Chikoy, Khilok, and Uda; on the left, the Dzhida and Temnik. The Orhon is 698 mi. (1,124 km.) long, with a basin of 51,280 sq.mi. (132,800 sq.km.); its main tributaries are the Iro, Hara, and Tola Gol; it is navigable upstream to the Iro. Karakorum, the ancient capital of the Mongol Empire, was situated near the upper Orhon. (R. E. F. S.)

SELENIUM is a chemical element closely allied in physical and chemical properties with sulfur. It was identified in 1818 by J. J. Berzelius, in Sweden. It had been found a year earlier in a red deposit that had collected on the floor of a room in which sulfur, obtained as a by-product from a copper mine, had been used; but its similarity to tellurium had caused it to be mistaken for that element. Since the name tellurium had been coined from *tellus*, the Latin word for "earth," Berzelius named his discovery after the moon (in Greek, *selene*).

In 1873, Willoughby Smith discovered that crystalline selenium develops a tremendous increase in electrical conductivity when exposed to light, regaining its resistance immediately when the light is shut off. This property eventually was applied in motion-picture sound tracks, television, the telegraphic transmission of photographs and many other devices depending on light-sensitive materials. (*See* below, *Selenium Cells and Rectifiers; see* also SELENIUM CELL.)

The symbol of selenium is Se; atomic number 34; atomic weight 78.96. It is a complex element with six valence electrons ($4s^2$, $4p^4$) in the outer (N) main level; six stable isotopes with mass numbers (in order of decreasing abundance) 80, 78, 76, 82, 77 and 74; and eight radioactive isotopes, including Se^{75} (half life, 127 days) and Se^{83} (half life, 25 min.) have been prepared.

Occurrence.—Selenium is widely distributed throughout the world, although in small quantities (10%–7% in igneous rocks), being the 69th element in order of abundance, between silver and argon. It rarely occurs native; frequently it accompanies native sulfur, but is commonly found in combination with the heavy metals as selenides and accompanying the more abundant metal sulfides. The important minerals are clausthalite, PbSe; eucairite, $(Ag,Cu)_2Se$; crookesite, $(CuAgTl)_2Se$; naumannite, Ag_2Se and zorgite (a complex selenide containing 31% Se). When any of the selenium-containing sulfide minerals are subjected to chemi-

cal processing operations, selenium appears as a by-product.

Physical Properties.—Selenium exists in several allotropic forms including a glassy form, two monoclinic (metalloid) forms and hexagonal (metallic) selenium, all stable to some extent at room temperature. Glassy or amorphous selenium is obtained when any form is heated above the melting point and subjected to rapid cooling. No well-defined freezing point is observed, the mass gradually thickening until at 40°–50° C. a glassy mass develops. The cold glassy product is brittle, exhibits conchoidal fracture and is only slightly soluble in carbon disulfide. Rapid reduction of a cold aqueous solution containing a selenium compound yields red amorphous selenium which changes to the gray form upon heating the solution. Orange to red modifications of monoclinic selenium are obtained when the red amorphous powder is extracted with carbon disulfide and this solution is evaporated and cooled. These modifications may be changed to gray metallic selenium by heating, the orange at about 110° C. and the red at about 125° C. Gray metallic selenium may also be prepared by allowing molten selenium to cool slowly to room temperature or by annealing other modifications slightly below the melting point. This form is completely insoluble in carbon disulfide, but soluble at higher temperatures in naphthalene, aniline and ethyl benzoate. It is this form of selenium which possesses the remarkable property of having its conductivity increased by light. That freshly precipitated red selenium may be amorphous is a matter of doubt. The metallic gray selenium has a melting point of 217° C. and a specific gravity of 4.79 (25° C.). It crystallizes in rhombohedral crystals in the hexagonal system.

Production.—In the United States and Canada the chief source of selenium is the anode slime from copper refineries, lesser amounts from the roasting of metallic sulfides. In most cases the selenium is isolated as selenious acid and elemental selenium is obtained by reduction with sulfur dioxide.

The chief producing countries are the U.S. and Canada; other sources include Sweden, Japan, and Zambia.

U.S. production of selenium in the 1960s was about 1,000,000 lb. per year. Consumption of selenium has been affected by high prices as well as sharp inroads by competitive materials. Germanium and silicon were substituted for selenium in rectifiers; tellurium replaced some selenium in rubber and stainless steel; and mercury and cadmium are substituted for selenium in the glass and pigment industries.

APPLICATIONS

In the 1960s by far the largest amount of selenium was used in the manufacture of electronic equipment, particularly power rectifiers. The chemical industry was a large consumer, the most important applications being in pigments, pharmaceuticals and rubber. The glass and steel industries also used large amounts, and there was a wide range of minor applications.

Selenium Cells and Rectifiers.—In 1873 it was found that selenium changed its electrical conductance under the influence of light. Shortly thereafter, a simple electric circuit containing a selenium element was shown to generate current when the selenium was exposed to light. Not until 1930 was this idea developed to a stage where it became useful in the form of a layer-barrier cell. Such a light-sensitive cell consists of a conducting metal back of copper, aluminum or brass, etc., coated with a thin film of metallic selenium, this in turn coated with a thin translucent layer of gold. A transparent filter usually protects the gold surface. One lead of the circuit is connected to the metal back and the other to the gold surface, the two leads being attached to a sensitive galvanometer or other measuring device. When light shines on the gold surface of the cell, sufficient electromotive force is developed to operate a sensitive galvanometer without any external amplifying circuit. This cell was used for photographic exposure meters, photoelectric colorimeters and other instruments designed to measure light. Although these cells have been improved, they are in general the photovoltaic type.

The dry rectifier differs from the selenium cell in the substitution of a low melting alloy such as Wood's metal for the gold film. During application of the alloy coat on the selenium or in annealing of the selenium, a surface develops or is provided between the selenium and the alloy which resists backward flow of alternating current. By allowing current to flow in only one direction the rectifier converts alternating current to direct current.

Such rectifiers are used for charging batteries, electroplating and operating a variety of direct current devices. When the rectifiers are connected in multiple units in series or parallel, they provide a wide variety of sizes and capacities. The cells operate at high efficiency over a wide range of loads.

Glass.—A large consumer of selenium is the glass industry. Selenium has replaced manganese as a glass decolorizer. The objectionable green colour produced in glass by iron is neutralized by the addition of a small amount of selenium. The addition of a larger amount of selenium, either as such or as sodium selenite, imparts to glass a clear red colour useful for signal lamps.

Rubber.—Selenium is used with sulfur in the vulcanization of certain special rubber products. Crystallization of sulfur in rubber may be induced by selenium because it is isomorphous with monoclinic sulfur. In this manner, metastable solutions of sulfur are prevented and initial rapid bloom (haze surface) of uncured stocks is eliminated. Selenium exerts a distinct accelerating action upon rubber-sulfur mixtures and increased abrasion resistance of certain vulcanizates.

Selenium Oxychloride as a Solvent.—The specific solvent properties of this reagent were studied by V. Lenher. The reagent is a solvent for certain natural and synthetic resins, fish oils, etc.; it helps to distinguish between saturated and unsaturated hydrocarbons, attacking the latter but not the former. In a mixture of benzene and heptane, it dissolves the former, whereas the latter floats unchanged. Selenium oxychloride, $SeOCl_2$, is a selective solvent for Cb_2O_5 in the presence of Ta_2O_5 and MoO_3 in the presence of WO_3. A solution of molybdenum trioxide in selenium oxychloride exhibits a photochemical effect; in the dark, the solution maintains the yellow colour of selenium oxychloride; exposed to light it changes to blue. The reaction is reversible.

Miscellaneous Uses.—Cadmium sulfoselenide forms a red pigment and is produced in relatively large amounts. Colours ranging from orange to maroon are obtained, depending on the method of preparation. The addition of a small amount of selenium to stainless steel, copper and copper-rich alloys improves machinability and is a commercially established practice. A protective coat on magnesium alloys may be made with selenium. Chemical uses include that of selenium dioxide as an oxidizing agent in organic reactions, and the use of selenium and copper selenite as catalysts in oxidizing reactions, such as the Kjeldahl digestion. Ferrous selenide is used as a catalyst in cracking petroleum. The use of selenium compounds on battery plates prevents sulfation and therefore permits higher charging rates. The use of selenium in fungicides and insecticides is limited, because of the possibility of contaminating food products. With the common use of mercury in laboratories and plants, the detection of small concentrations of mercury has become important. A selenium-sulfur mixture blackens quickly in the presence of mercury vapour and is used to indicate exposure of workers to mercury fumes. Selenium has been used in flameproofing of textiles and certain cable coatings.

Some species of plants are not only tolerant of selenium but actually require selenium for growth and development. Since selenium occurs with uranium in certain types of deposits, the presence of plants which require selenium for growth may indicate the presence of uranium in a deposit. Such plants are sometimes called indicator plants. These plants may contain as much as 1.5% of selenium and have an offensive garliclike odour.

CHEMICAL PROPERTIES AND COMPOUNDS

Selenium reactions lie intermediate between sulfur and tellurium. At the boiling point selenium vapours consist of mixtures of Se_8 and Se_2. Heated in oxygen the element burns with a blue flame, selenium dioxide being formed. Direct combination of the element with hydrogen, oxygen, halogens and many metals is common. The halogen compounds are hydrolyzable but not so easily as comparable sulfur compounds.

Selenium is a weaker reducing agent than sulfur. Solution in concentrated sulfuric acid yields a green solution of $SeSO_3$. The acid-forming tendencies of the element are most pronounced in the higher valences. The valence types of selenium compounds are −2, 0, +2, +4, +6. Gray selenium has a melting point of 217° C.; heat of fusion 1.56 kg.cal. per gram; heat capacity 6.0 (25° C.) cal. per gram-atom; entropy at 25° C., eutectic units 10.0; and magnetic susceptibility -0.32×10^{-6}.

Inorganic Compounds.—*Hydrogen selenide,* H_2Se, is a colourless gas which has a disagreeable odour and is extremely toxic. It has a boiling point of −41.3° C. and a melting point of −64° C. It burns with a blue flame, giving either red selenium or white selenium dioxide, depending on the amount of oxygen present. The gas is prepared by dropping water on aluminum selenide, the latter being prepared by direct combination of selenium and powdered aluminum. Hydrogen selenide is less stable and is a stronger reducing agent than hydrogen sulfide. This behaviour may be associated with the fact that selenium has a larger atomic size than sulfur.

Metallic selenides are produced by direct combination of metals with selenium or by precipitation from solutions of metallic salts by hydrogen selenide. The alkali selenides are colourless but become red by addition of more selenium to form polyselenides such as Na_2Se_2.

Selenium dioxide, SeO_2, is easily prepared by burning selenium in an excess of oxygen. Impure selenium dioxide (called whispers) is obtained from dust chambers which catch the dust from roasting certain metallic sulfides. This material is contaminated with selenium and other impurities and may be purified by addition of nitric acid, removal of the excess nitric acid by fuming and finally obtaining the selenium dioxide by sublimation. The dioxide crystallizes in long colourless crystals, melts under pressure at 340° C. and dissolves in water to form selenious acid.

Selenium trioxide, SeO_3, has been prepared by the action of sulfur trioxide on potassium selenate and also by the vacuum sublimation of a 1:1 mixture of selenic acid and phosphorus pentoxide.

Selenium monoxide is a definite oxide but has been identified only in the gaseous state by spectroscopic means.

Selenic acid, H_2SeO_4, may be prepared by addition of bromine to silver selenite. This acid, the analogue of sulfuric acid, is usually seen as a sirupy liquid, but has been obtained solid (melting point 58° C.). The solid acid is prepared by desiccation of a strong selenic acid solution. It cannot be obtained pure by distillation since some of the selenic acid decomposes to form selenious acid. Selenic acid has the noteworthy property of dissolving gold in the presence of oxygen. Like telluric acid, it oxidizes hydrochloric acid to give free chlorine. The selenates are similar to the sulfates; the soluble selenates are stronger oxidizing agents.

Selenium tetrafluoride, SeF_4, was obtained in the pure state (1928 by E. B. R. Prideaux and C. B. Cox) by the interaction of selenium tetrachloride and silver fluoride. It is a colourless liquid boiling at 93° C. and melting at −13.2° C. Its specific gravity is 2.77. It attacks glass and is completely hydrolyzed by water to selenious and hydrofluoric acid.

Chlorides.—Selenium forms a number of chlorides. Diselenium dichloride, Se_2Cl_2, a brownish-yellow liquid with pungent odour, is decomposed by water into hydrochloric and selenious acids with elimination of red selenium. Selenium tetrachloride, $SeCl_4$, a colourless crystalline mass which vapourizes without melting, is produced by burning selenium in chlorine. Selenium oxychloride, $SeOCl_2$, a pale yellow liquid boiling at 177.2° C. and melting at 8.5° C., is prepared by direct chlorination of a mixture of selenium and selenium dioxide. The impure liquid is purified by distillation. Selenium substitutes for oxygen in a number of acids, forming such compounds as sodium selenocyanate.

Organic Compounds.—In many instances the equivalent of sulfur compounds are known. The following types of aliphatic compounds are known: types RSeH, R_2Se, RSeR′, and R_2Se_2, complex compounds of platinum and platinum halides with dialkyl selenides and types R_2SeX_2 and R_2SeX, R representing a variety of alkyl radicals and X various halogens. Compounds derived from aldehydes and ketones are similar to selenoacetaldehyde, CH_3CHSe, and diselenoacetone $(CH_3.CS_e.CH_3)_2$. Selenoacetic, CH_3COSeH, and ethyl selenoformic, C_2H_5COSeH, are examples of the relatively simple aliphatic acids, and 2:4 dinitrophenylselenoacetic acid is an example of the more complex. Nitric acid oxidizes dialkyl diselenides to alkyl seleninic acids.

A large number of aromatic derivatives of selenium have been prepared. Types in which R represents a variety of aryl groups are RSeH, R_2Se, R′SeR and RSe.SeR. The interaction of selenium tetrachloride and benzene in the presence of aluminum chloride yields diaryl selenides and diaryldiselenides. Diarylsulfones heated with precipitated selenium yield diaryl selenides, mixed selenides being formed if the radicals in the sulfones are different. Compounds of the types R_2SeX_2 and R_2SeO, R being an aryl group, are illustrated by diphenyl selenium dibromide and diphenyl selenoxide. Although bromine reacts directly with diaryl selenides in carbon disulphide to form bromides, the direct union of chlorine is less usual. Nitric acid reacts with diaryl selenides or their dibromides to form nitrates. The dibromides treated with moist silver oxide yield hydroxides. When sodium hydroxide is used, the diaryl selenoxides, RSeO, are obtained. Many mixed compounds are known. Examples are phenylmethylselenium bromoiodide and phenylmethylselenium dihydroxide. A comprehensive presentation of organometallic compounds was provided by Newton Friend and A. E. Goddard (1937).

Detection and Estimation of Selenium.—Selenium is precipitated from its inorganic compounds by hydrogen sulfide and is redissolved by ammonium sulfide. A characteristic test is the precipitation of red selenium from a hydrochloric acid solution by sulfur dioxide, hydrazine, hydroxylamine, etc. The gravimetric estimation is made by weighing this precipitate after it has been boiled to convert it to the gray modification. Selenium may be determined iodometrically, and selenious acid may be titrated with permanganate. Selenates may be estimated by distillation with hydrochloric acid. The liberated chlorine is collected in potassium iodide and the iodine thus liberated is titrated with thiosulfate. An excess of hydrazine can be added to selenious acid and the excess reagent titrated with potassium iodate to an ICI end point. Selenious acid may be reduced by hydriodic acid and the liberated iodine titrated with thiosulfate. Thiosulfate is used as a reducing agent for selenious acid and the excess reagent titrated with iodine. Tellurium must first be removed or accounted for. Instrumental methods include potentiometric titration, polarographic determination, coulometric and spectrophotometric measurements.

Medical Aspects.—*Selenium in Soils and Plants.*—Although the toxic nature of selenium was recognized as early as 1842, it was not until 1929 that a thorough study was initiated to determine the effects of the element in animal and human hygiene. It is recognized that plants grown on seleniferous soils may absorb selenium (*see* LOCOWEED). When used as food for animals or humans, the plants are toxic, causing either chronic or fatal poisoning. Affected areas have been surveyed and in some cases planting discontinued. Wheat samples grown in some areas contained 30 parts per million of selenium; only 10 to 20 parts per million are necessary to produce chronic poisoning in cattle. Although the hull, bran and patent flour become separated in milling operations, enough selenium can remain in the flour to be a hazard to humans, particularly if the wheat is grown on highly seleniferous soils. Selenium poisoning in horses is accompanied by loss of hair from tail and mane and by abnormal hoof growth; extreme cases produce blind staggers or even death. In humans selenium may concentrate in the lungs, liver, kidney or spleen. Occupational dermatitis is a mild form of poisoning. Few cases of death have been reported. Recent studies indicate arsenic as a possible inhibitor for selenium poisoning. It is known that soils which are leached by abundant ground water lose some selenium and that plants grown in areas of plentiful rainfall contain less selenium, even though the soil contains the element. The Colorado river, for example, carries away selenium from certain irrigated areas in the western United States. It is interesting to note that bot-

tom deposits and growths in the Gulf of California and the Gulf of Mexico contain notable amounts of selenium.

Protection Against Liver Necrosis.—Klaus Schwarz and C. M. Foltz and others have reported that liver necrosis in rats may result from low cystine and simultaneous deficiency in vitamin E and factor 3. As little as 13.33 micrograms of sodium selenite in 100 grams of diet afford complete protection against liver necrosis. The dose necessary for protection is less than 1% of the toxic dose.

SELENIUM CELL. The selenium cell is a photoelectric device used to generate or control an electric current through the influence of light falling upon the cell. Selenium photocells are commonly used in photographic exposure meters, burglar alarms, electronic door opening and counting devices, electronic control systems in factory assembly lines and industrial colour perceptors. In some ways (colour perception, sensitivity) the performance of selenium photocells is superior to that of vacuum-tube photocells. (For a discussion of the latter, *see* PHOTOELECTRICITY.) The fact that selenium cells do not respond instantaneously to changes in stimuli, however, makes them unsuitable for certain purposes, such as high fidelity sound reproduction on film.

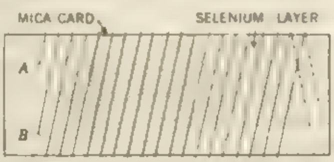

FIG. 1.—THE SELENIUM LAYER OF A SIEMENS PHOTOCONDUCTIVITY CELL CONDUCTS CURRENT BETWEEN THE TURNS OF WIRE (A AND B)

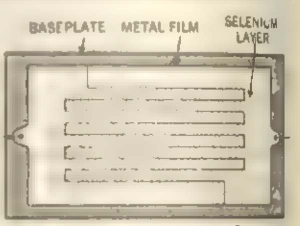
The photoelectric properties of selenium, a nonmetallic element, are exhibited in two ways: (1) When light falls on a specimen of crystalline selenium the electrical conductance of the selenium is increased. A device employing this effect is called a selenium photoconductive cell. If such a cell is connected in a circuit with a battery, a small current, called the dark current, will flow if the cell is not illuminated. If the cell is illuminated, the increased conductance of the selenium element permits a larger current to flow. The increase in current may then be used to operate a relay, produce an indication on a current meter or perform some other useful function in the circuit associated with the cell. (2) When selenium is placed in contact with an electrode made of a suitable metal, the contact has the ability to generate an electromotive force (E.M.F.) when exposed to light. The illuminated contact thus behaves like a battery, with the selenium becoming the positive terminal and the contacting metal becoming the negative terminal. A device employing this property of selenium is called a selenium photovoltaic cell. Such a cell can be used as a photoelectric battery in a practical electrical circuit.

The photoconductivity effect in selenium was first reported in Great Britain by Willoughby Smith in 1873. Selenium was the first solid material found to exhibit this effect. Following this discovery a number of photoconductivity cell designs were developed. The discovery of the photovoltaic effect at contacts between selenium and various metals was first reported by W. G. Adams and R. E. Day in England in 1877. Shortly thereafter, in 1883, Charles E. Fritts in the U.S. constructed a practical selenium photovoltaic cell which embodied most of the features found in cells of modern design.

Unfortunately, much of this early work either went unrecognized or was lost to sight; and the selenium photovoltaic cell had to be "rediscovered" later.

Selenium is one of the elementary chemical substances (*see* SELENIUM). It melts at 217.4° C. When cooled from the molten state it "solidifies" into a hard, brittle, noncrystalline material in which its physical condition is actually that of an extremely viscous liquid, like glass. In this condition it is called amorphous selenium. The electrical resistance of amorphous selenium is so high as to classify it as an insulator; and in the amorphous state selenium exhibits no usable photoelectric behaviour. If a specimen of amorphous selenium is heat treated at any temperature between about 120° C. and its melting point, however, conversion to the more useful gray crystalline form occurs. The electrical resistance of gray crystalline selenium between opposite faces of a 1-cm. cube is about 1,000 ohms, the exact value depending on impurity content and on the details of the annealing treatment by which the specimen was converted to the crystalline form. It is in this form that selenium is employed in the structures of photoconductive and photovoltaic cells.



ADAPTED FROM G. P. BARNARD "THE SELENIUM CELL", BY COURTESY OF CONSTABLE & CO. LTD., LONDON

FIG. 2.—PHOTOCONDUCTIVITY CELL IN WHICH THE SELENIUM LAYER BRIDGES THE GROOVE SEPARATING TWO SECTIONS OF A METAL FILM

Photoconductive Cells.—The basic parts of a selenium photoconductive cell consist of an active portion of gray crystalline selenium, so disposed that the light to be detected or measured can fall upon it, with metal contacts to the selenium permitting current to flow into, through and out of it. One of the simplest of these cells was devised by the German inventor and industrialist Werner Siemens in 1876. In the Siemens cell two fine copper wires are wound around a rectangular mica card as shown in the sketch in Fig. 1. The windings are separated so that the wires do not touch each other anywhere. This assembly is then placed on a hot plate and raised to a temperature a few degrees higher than the melting point of selenium. A piece of selenium placed on this assembly soon melts to a molasseslike liquid, in which condition it is spread in a thin film over the upper surface of the mica, completely embedding the copper wires. The assembly is then removed from the hot plate and allowed to cool, the selenium hardening into an amorphous layer. To convert the selenium to the gray crystalline form, the assembly is again heated for several hours at a temperature of about 180° C.

Electrical connections to this cell are made at the two contacts *A* and *B*; the other ends of these wires are left open circuited. Any current flowing between these terminals must flow through the selenium film between adjacent turns of the wires. Illumination of the selenium film then increases the total parallel conductance of the cell between these terminals. A Siemens-type cell with a selenium layer area of 1 sq.in. may exhibit a resistance of one or two megohms in complete darkness. When exposed to full sunlight the cell resistance drops to a few thousand ohms.

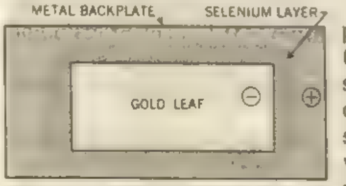


FIG. 3.—FRITTS'S PHOTOVOLTAIC CELL IN WHICH AN ELECTROMOTIVE FORCE IS GENERATED BETWEEN THE GOLD LEAF AND THE BACKPLATE UPON EXPOSURE TO LIGHT

A different form of selenium photoconductive cell, shown in the sketch in Fig. 2, employs a support plate made of slate, glass or other insulating material. One side of the support plate is provided with a film of deposited metal, which is then scribed through with a sharp tool, in a zigzag line, in such a way that the metal deposit is divided into two sections separated and insulated from each other by the zigzag line. A thin film of crystalline selenium is then laid down on the surface of the metal deposit, filling in the scribed line. Light falling anywhere on the selenium increases conduction between the two portions of the metal deposit which wires connect to the cell.

In their operation selenium photocells have some advantages over vacuum-tube photocells; they also display some disadvantages. A properly made selenium cell may be a hundred times more sensitive to a given amount of illumination than a vacuum-

tube photocell. Also, the selenium cell is responsive to light throughout the entire range of colours visible to the human eye, while many vacuum-tube photocells, particularly the more sensitive ones, are responsive only to light of the green, blue or purple regions of the colour spectrum. The response of a selenium photocell, on the other hand, is not directly proportional to the amount of light falling upon it. Instead, the change in conductance is proportional to the square root of the light flux on the cell. This relationship means that the cell is relatively more sensitive for the lower levels of light intensity.

Another disadvantage exhibited by the selenium photoconductivity cell is the time lag of its response. When a selenium cell is suddenly exposed to light, the change in conductance is not instantaneous. It may require a thousandth of a second or more for the cell conductance to rise to the new value appropriate to the illuminated condition. Similarly, if the light is suddenly cut off, a comparable length of time is required for the conductance to resume its dark value. This time lag in response means that the cell cannot follow the rapid fluctuations of light intensity which must be dealt with, for example, in the high fidelity reproduction of sound on film.

Selenium photoconductivity cells must find most of their uses, therefore, in applications where the cell must distinguish between light on and light off, or where the cell is exposed to light which is either steady or else varying at frequencies lower than those corresponding to speech or music.

The physics of the photoconductivity effect is easy to describe. The electrical conductance of any substance is proportional, among other things, to the number of electronic particles per unit volume which are free to move about within the substance and which, by their motion when voltage is applied, cause a current to flow. Selenium has a relatively small number of such free particles available in the dark. However, when light shines on a specimen of selenium and is absorbed by it, the energy of the radiation is expended in the freeing of additional numbers of conducting particles which increase the total number available and hence increase the electrical conductance of the illuminated specimen.

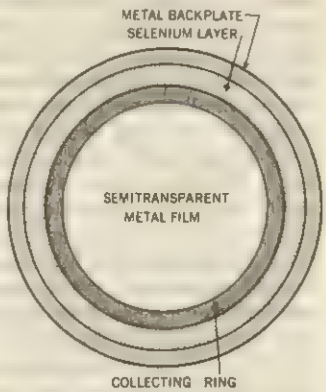

FIG. 4.—MODERN PHOTOVOLTAIC CELL SIMILAR TO FRITTS'S CELL (FIG. 3)

Photovoltaic Cells.—By far the most extensive modern use of selenium in photoelectric cells is in devices of the photovoltaic or self-generating variety. Fig. 3 shows a sketch of an early selenium photovoltaic cell constructed by Fritts. This cell made use of a thin layer of crystalline selenium spread out on the surface of a metal base plate. On the outer surface of the selenium layer was placed a translucent film of gold leaf. When the cell was illuminated from the gold leaf side, Fritts observed that an electromotive force (E.M.F.) appeared between the gold leaf and the base plate metal. If the gold leaf and the plate were connected through an external circuit, a current flowed as long as the illumination of the cell was continued.

Modern selenium photovoltaic cells are but little different from Fritts's early model. A thin layer of selenium is applied to one side of a supporting base plate of iron, nickel or aluminum. Instead of spreading the molten selenium onto the base plate at an elevated temperature, however, present-day manufacturers apply the selenium film by vapour deposition in vacuum. Following the customary heat treatment, an outer contact of gold is then applied to the surface of the selenium layer, again by vapour deposition in vacuum. This gold film must be thin enough to permit a substantial fraction of the light to penetrate to the gold-selenium contact, yet thick enough to permit good lateral conductance for the current which the cell is to deliver. Contact to the gold film is provided in modern design by a built-up collecting ring of painted-on graphite or more heavily deposited metal around the outer periphery of the gold film.

Fig. 4 shows a section sketch of a modern selenium photovoltaic cell showing these features. A cell of this construction will deliver an open-circuit E.M.F. of 0.3 or 0.4 volt in light of 100 foot-candles intensity. Under the same conditions of illumination, such a cell having an area of 1 sq.in. will deliver a current of 250 microamperes into a 1,000 ohm external resistance. Fig. 5 shows a family of characteristics for a modern cell having an effective area of about 2 sq.in. Each curve gives the output current as a function of light intensity for a particular value of external circuit resistance. Note that in no case is the current linearly proportional to circuit resistance, but is more nearly so for the lower values of resistance. By short-circuiting the cell, one could obtain a characteristic almost completely linear, but such a circuit arrangement would draw no useful power from the cell and would correspond, therefore, to a very inefficient use of the cell.

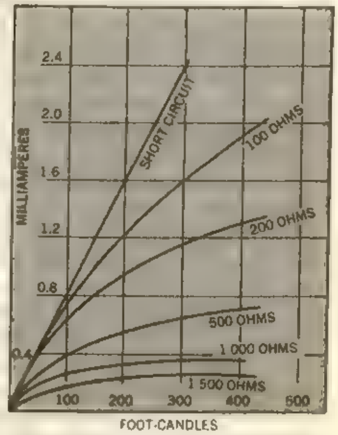

FIG. 5.—RELATIONSHIPS BETWEEN OUTPUT CURRENT AND LIGHT INTENSITY FOR A MODERN SELENIUM PHOTOVOLTAIC CELL WITH DIFFERENT EXTERNAL CIRCUIT RESISTANCES

The time lag exhibited by a selenium photovoltaic cell between sudden exposure to light and the development of the corresponding output E.M.F. is comparable with the time lags encountered in selenium photoconductivity cells. If a photovoltaic cell is exposed to interrupted light of constant intensity but variable frequency of interruption, the A.C. response of the cell drops to half its low-frequency value if the interruption frequency is somewhere in the range from 1 kc. to 10 kc.

The physics of the photovoltaic effect is somewhat more complicated than that underlying photoconductivity. The seat of the E.M.F. is the contact between the selenium and the overlying gold film electrode. The photoelectric property of this contact comes about because of the so-called contact potential difference between the selenium and the gold. This contact potential difference appears across a thin layer in the selenium immediately adjacent to the gold contact and within a distance of 10^{-5} cm. of the actual gold-selenium boundary. Inside this layer, called the barrier layer, the physical properties of the selenium are different from those in the rest of the selenium film. When the contact is illuminated, charged electronic particles are liberated by the absorption of light in the barrier layer. These particles, acting like ions in the electrolyte of an ordinary battery, are pulled by the electric field of the barrier contact potential difference in such a direction as to cause a negative charging up of the gold electrode. From this electrode, then, electrons can flow around the external circuit, back into the support plate metal, and thence into the other side of the selenium layer, as long as the illumination is continued.

The photoelectric properties of a selenium photovoltaic cell can be described in terms of the electrical equivalent circuit shown in Fig. 6. The gold-selenium contact barrier has three parallel properties: a barrier capacitance C; a barrier resistance R; and an effective barrier battery B having the property of generating not a voltage but rather a current proportional to the amount of light falling on the cell and numerically equal to the product of a constant of proportionality K by the light intensity

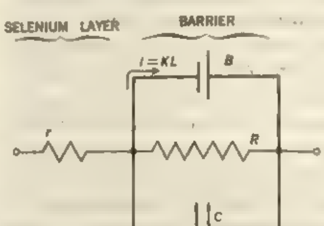

FIG. 6.—ELECTRICAL EQUIVALENT CIRCUIT EXHIBITING THE SAME TERMINAL BEHAVIOUR SHOWN BY AN ILLUMINATED PHOTOVOLTAIC CELL

L. For modern commercial selenium photovoltaic cells, *K* has values in the neighbourhood of half a milliampere per lumen. In series with the barrier is the resistance *r* of the selenium layer outside the barrier. When the cell is illuminated, the current generated by the equivalent barrier battery divides, part going around the external circuit and the rest leaking backward internally across the barrier resistance *R*. Unfortunately, this barrier resistance is not constant, but decreases for higher values of the E.M.F. appearing at the cell terminals. Thus, for a constant load resistance in the external circuit, if the illumination is made brighter *R* becomes smaller and a larger fraction of the equivalent battery current is lost by internal leakage across *R*. This variable loss explains the nonlinearity of the curves of Fig. 5.

The barrier capacitance *C* has virtually no effect on the performance of the cell for exposure to steady light; but for interrupted light or fluctuating light this capacitance has a bypassing effect which reduces the A.C. output of the photocell. The reduction is more severe the higher the frequency of interruption or fluctuation of the light. The magnitude of this capacitance is about one-half microfarad per square inch.

Incidental Properties.—Selenium photoconductive and photovoltaic cells have approximately the same colour responses. Selenium cells are responsive to all wave lengths in the visible spectrum and also to a short range of wave lengths in the near ultraviolet. The greatest sensitivity appears in the orange and orange-red spectral region.

The output of a selenium cell is dependent on temperature, the dependence being to a considerable extent determined by the nature of the associated circuit. In a selenium photoconductivity cell the magnitude of the dark conductance increases about 2% per degree rise in temperature, while the conductance change upon illumination decreases with increasing temperature by about 1% per degree. The chief temperature dependence of the selenium photovoltaic cell is exhibited by the barrier resistance *R*, which decreases with increasing temperature (6% or 7% per degree).

A selenium photovoltaic cell will deteriorate in sensitivity if it is exposed for long periods to a highly humid atmosphere. The modern practice of coating the cell surfaces with a protective lacquer film slows down this deterioration but does not prevent it altogether. Some manufacturers have experimented with complete hermetic sealing of the cell elements.

Uses of Selenium Cells.—Probably the most extensive use of selenium cells is in the construction of portable exposure meters used by photographers. In this application a photovoltaic cell is used in a self-contained package with a moving coil meter and a dial or table for converting the meter reading to the correct exposure. Selenium cells have a wide range of industrial applications for distinguishing between light on and light off. For example, a selenium cell may be placed near a light source so that the passage of an article along a conveyer belt interrupts the light beam and causes registry on a counter. A safety interlock for stamping and pressing machines can be arranged with a light source and photocell so placed that as long as a workman's hands are between the dies the light beam is broken and the circuit controlling the operation of the machine is inhibited.

Another on-off application of selenium cells is found in burglar alarm systems where the interruption of a beam of light across a doorway or window trips an alarm. In department stores and public buildings a closely allied application is coming into increasing use, in which a door is automatically opened when a light beam is broken by an approaching person. Similar systems are used for counting visitors at exhibitions or counting automobiles to obtain traffic data.

There are many industrial processes which can be monitored or controlled with the aid of selenium photocells in suitable circuits. Depth of colour is often an indication of the correct proportions of a mixture, of the thoroughness of mixing or of the stage of a chemical reaction. In these cases photocells have proved more vigilant and accurate as colour perceptors than the human eye, and their employment has resulted in better product control in the chemical, pigment and textile industries.

SELEUCIA (SELEUKEIA), the name of several Hellenistic cities named or renamed after the founder of the Seleucid dynasty, Seleucus I Nicator (ruled 312–280 B.C.).

SELEUCIA ON THE TIGRIS lay on the right bank of the Tigris River about 20 mi. SE of Baghdad, at the mouth of the "royal canal" connecting the Tigris and the Euphrates. The city was founded by Seleucus I as his eastern capital, and its building, mainly of materials brought from Babylon, marks the definite end of Babylon. Seleucia is closely associated with Hellenistic culture in Mesopotamia. It was peopled with Macedonians and Greeks, but its population also included Jews and Syrians; it was definitely a cosmopolitan city. Pliny gives the population as 600,000. During the Parthian domination the city continued to be the foremost city of the east in position and trade. Preserving its Greek sympathies, it was definitely opposed to and at times in open rebellion against the Parthian kings, who favoured the neighbouring Ctesiphon (*q.v.*) and founded Vologesias or Vologesocerta as a rival canal port. Seleucia eventually was burned by Avidius Cassius in A.D. 165, at which time it is said to have had at least 300,000 inhabitants. The destruction of the city marks the end of Hellenism in Mesopotamia. Septimus Severus, in his Parthian campaign of 198, found the site completely abandoned, and in 363 Julian's soldiers hunted wild game in marshes in its vicinity. Nothing remains above ground; excavation of the site (then called Tel Umar) during 1927–32 was sponsored by the University of Michigan and the Toledo and Cleveland museums of art, with interesting but unspectacular results.

SELEUCIA PIERIA, in Syria, a port and frontier fortress on the Cilician border (near modern Samandag, Turkey), lay 4 mi. N of the mouth of the Orontes River and was the port of Antioch (*q.v.*). With Antioch, Apamea, and Laodicea it formed the Syrian tetrapolis. The town occupies the rocky slopes of Musa Dagi, and the great Roman flood diversion, a deep cutting through the rock, still survives. The harbour is complete but high and dry. The city was of considerable military importance during the wars between the Ptolemies and the Seleucids and was recognized as an independent city later by the Romans.

SELEUCIA TRACHEOTIS or TRACHEA (modern Silifke, Icel il, Turk.), a city in Cilicia, lay on the Calycadnus River (modern Goksu Nehri), a few miles from the mouth, doubtless as a protection against attacks from the sea. There are ruins of a castle on the acropolis, and the city fortifications, a large rock-cut tank, and an extensive necropolis are all well preserved. The city was at one time a port serving Isauria and was entitled to strike its own coinage. It was built near an old site by Seleucus I. During the Third Crusade Frederick Barbarossa was drowned in crossing the river at this point (A.D. 1190). The city was captured by the Turks in the 13th century. It is now the centre of a fertile plain, which has been irrigated by modern works in the local river.

Several other towns also bore the name of Seleucia, among them Seleucia on the upper Euphrates, near Samosata; in the Persian province of Margiana, which was renamed by Antiochus I, having been previously called Alexandria after its original founder, Alexander the Great (*see* ALEXANDRIA: *Alexandria in Margiana*; and MERV); in Pisidia; in Pamphylia; Seleucia Sidera ("the iron") in Phrygia; on the Belus in Syria; and in Caria (Tralles; *q.v.*). (WM. C. B.; X.)

SELEUCID DYNASTY, a line of kings who reigned in nearer Asia from 312 to 64 B.C. as one of the successor dynasties of Alexander the Great.

The Seleucid Empire reached its greatest extent under the first of the kings, Seleucus (*q.v.*) I Nicator. At his death (280) it embraced the Iranian provinces as far to the east as the Hindu Kush Range and the valley of the Oxus River, Media, Babylonia, Mesopotamia, Cappadocia, the whole of Asia Minor (apart from Armenia, Pontus, Paphlagonia and Bithynia), Syria, and, in Europe, parts of Hellespontine Thrace. During the 3rd century B.C. (after 280) much ground was lost in Asia Minor either through

Greek cities on the Aegean coast throwing off their allegiance or through the emergence of new independent states (such as Pergamum and Cappadocia), or through the cession of territory to the Celtic invaders (*see* GALATIA) and the Bithynian and Pontic kings (*see* BITHYNIA; PONTUS). The hill country of the Taurus Range in southern Asia Minor was never properly subjugated, and the Seleucid possessions to the north and west of Cilicia were reduced, before the end of the 3rd century, to large parts of Caria, Lydia, Aeolis, and the Troad (all on the Aegean seaboard), connected by a narrow corridor running through southern Phrygia and Lycaonia to Cilicia and Syria.

In the northeastern area of the empire, Parthia, Bactria, and Sogdiana became independent after the middle of the 3rd century. The submission of these districts to Antiochus III later (209–206) was of only passing effect. Coele-Syria (Lebanon) and Palestine had been fought over by the Seleucids and the Ptolemaic kings of Egypt ever since the accession of Antiochus I (280); not until the reign of Antiochus III did they pass finally into Seleucid possession (*c.* 200). This acquisition and the short-lived subjugation of Armenia and the former eastern provinces of the empire counterbalanced the loss of all Asia Minor north of Mt. Taurus by the Treaty of Apamea (188), which resulted from the defeat of Antiochus III at the hands of Rome and Pergamum.

After the death of Antiochus IV (163) the small state of Commagene in northern Syria emerged as an independent kingdom, as did Judaea in Palestine. In the east all the provinces to the east of Media, Susiana, and Persis had been lost by the same date, either to the Parthians or to the kings of Bactria. In 145 Ptolemy VI of Egypt reoccupied Coele-Syria and Palestine. In 141 or 140 the Parthians annexed Babylonia and the southern part of Mesopotamia. By then everything to the east of the Euphrates, apart from a small foothold in northern Mesopotamia, had been lost; and the utter failure of the expeditions led by Demetrius II in 140–139 and Antiochus VII in 130–129 to recover the lost provinces meant that the kingdom was reduced to Syria and eastern Cilicia. Even this limited area was held only precariously in the final period of the dynasty (126–64 B.C.).

To the Romans the Seleucids were known as the kings of Syria, and many modern writers have followed Roman practice in so describing them. From the above account, however, it will be seen that this description is appropriate solely to the kings who ruled after the Parthian occupation of Babylon. At the same time it should be noted that Syria had generally been the royal residence ever since Seleucus I had founded Antioch on the Orontes as his capital. Seleucia on the Tigris, the residence of the governor of the eastern provinces (often the crown prince), held the position of a second capital. Significantly, the principal satrapy, or administrative division, of Syria was named Seleucis. Besides Antioch on the Orontes the Seleucids founded many other important new cities in Syria (*see* SYRIA) and made strenuous efforts to give it a large Greek population. Through the presence there of the court and by reason of its strategic position, Syria undoubtedly constituted the centre of the Seleucid Empire and surpassed in political importance all its other regions.

The Seleucids adopted all the outward form of Macedonian kingship (*see* HELLENISTIC AGE). Over their Asiatic subjects they claimed absolute power by the right of conquest. To the Greeks and Macedonians within their empire they were leaders rather than masters; but the traditional right of the Macedonian Army to confirm successions to the throne and declarations of war was ignored in practice, and the Greek cities, though many of them enjoyed the status of free allies of the king and all retained the forms of civic autonomy, were expected to carry out the king's wishes. The powerlessness of the later Seleucids led to the Syrian cities' asserting their independence in a manner that would have been unthinkable before the death of Antiochus IV (163). The absolutism practised by the kings is reflected in the establishment, not later than the reign of Antiochus II Theos (*c.* 261–*c.* 247), of a state cult of the living ruler.

The kings made themselves personally responsible for all matters of state. To assist them there was a small number of ministers in charge of particular departments of government. One of these, *ho epi ton pragmaton* ("the man in charge of things"), may have acted as chief minister under the king; possibly, however, the title merely denotes a regent acting in the king's absence. Indeed, virtually nothing is known of the central administration of the kingdom. In provincial government, wisely, no attempt was made at enforcing too strict a control over the numerous provinces, some of which lay at a great distance from the centre of the empire.

The large regional unit of the satrapy, inherited from the Persian Empire, was retained in the western half of the kingdom. Thus in Asia Minor the following Seleucid satrapies are known: Hellespontine Phrygia, Phrygia, Lydia, Caria, and Cilicia. East of the Euphrates the satrapies were divided into smaller areas—eparchies and hyparchies. There, the administration was in three stages: from the satrap's headquarters to the seat of the officer governing the hyparchy, the eparchy forming the link between satrapy and hyparchy. In some cases satrapies were governed by generals (strategi), in others the satrap himself exercised military power (though H. Bengtson argues that every satrapy contained both a satrap and a general). Matters relating to finance within the satrapy were assigned to a separate official.

Little is known of the forms of taxation in the Seleucid Empire. Perhaps from motives of expediency, the kings did not insist upon a uniform system. Though certainly less exacting than the Ptolemaic kings of Egypt in the demands they made on their subjects, the Seleucids must have drawn large revenues. The expenses involved in maintaining the court and army were heavy, but the surplus of revenue and the general prosperity of the kingdom were sufficient to make the kings and the leading men in the state very rich. All the categories within the empire—subject kings, dynasts, peoples, and cities—were liable to taxation in money or kind, but only in the case of the royal domains, where the land was cultivated by the royal serfs ("the king's people"), were taxes collected directly by royal officials; in all other cases collection was indirect and by stages. In accordance with their preference for a decentralized mode of government, and in order to encourage the growth of city life, the Seleucids commonly allotted large tracts of royal land to Greek cities and compelled feudal landowners and temple states to do the same. This process led to the gradual emancipation of the serfs on the land affected.

The Seleucid Army had as its nucleus the infantry phalanx, a traditional feature of all the Macedonian states. Its members were recruited from the military colonists who dwelt at various places throughout the empire, a hereditary class of Macedonian and Greek ancestry. To supplement the phalanx, the Seleucids relied upon mercenaries (Greeks, Galatians, and Jews, among others) rather than upon native levies, although contingents of the latter were also employed upon occasion. The army was large and frequently on active service; its upkeep was probably the principal charge upon the kingdom's revenue. By contrast, the fleet was of only slight importance; squadrons were maintained in the Mediterranean and the Persian Gulf.

While certain important regions on the confines of the empire broke away at various times and attained complete independence under their own rulers (*see* ATTALID DYNASTY; BACTRIA; CAPPADOCIA; COMMAGENE; PARTHIA), there were also many semiautonomous units in all parts of the realm, including those Greek cities that enjoyed full self-government. Temple states, all of very ancient origin, were particularly numerous in Asia Minor; examples occur too in Syria and elsewhere. The early Seleucids, as protectors of all varieties of religion, tolerated their existence while endeavouring to diminish the power of the priest-rulers by transferring temple land to neighbouring Greek cities or to new military colonies. The later Seleucids, however, were not strong enough to assert such control and the priests grew in authority once more, as they did in Egypt under the later Ptolemies.

Of all the Hellenistic dynasties the Seleucids were by far the most active in the foundation of new Greek settlements, whether military colonies or cities. In Asia Minor their foundations or refoundations included: Stratonicia, Thyateira, Blaundus, Seleucia (Tralles), Antioch (Alabanda) (all in Lydia and Caria); Apamea (Celaenae), Seleucia the Iron, Apollonia, Laodicea Combusta,

Seleucia Trachea, Antioch (Tarsus), Antioch (Adana), Seleucia (Mopsuestia) (all situated, in order from west to east, from Phrygia to Cilicia). (For foundations in other regions of the kingdom *see* PERSIAN HISTORY: *Hellenistic Period;* MESOPOTAMIA: *Seleucids, Parthians and Romans;* SYRIA: *History: Hellenistic and Roman Syria.*)

The purpose of the Seleucid kings in creating such an extensive network of Greek settlement was probably the limited aim of buttressing their authority over the masses of their native subjects by establishing among them centres of power upon which they could safely rely. They could not have expected that the centres of Hellenism so created would bring about the hellenization of the native peoples. In fact very few Asiatics became hellenized in any more than a superficial way; the cultural gap was too wide to allow easy assimilation to take place. The racial cleavage was recognized in the provision of separate courts of law for Greeks and Asiatics. Moreover, for all the unceasing efforts of the kings to maintain and increase Greek immigration into their kingdom, the flow of new settlers was never enough to reduce noticeably the great preponderance of the Asiatic peoples.

Of the other achievements of the Seleucids two may be noted. (1) their promotion of commerce; not only within their own kingdom but also internationally, by protecting and encouraging the caravan trade between central Asia and the Mediterranean and the trade by sea with India by way of the Persian Gulf; (2) their introduction of a calendar which supplied the universal need of a readily comprehensible system of dating. This calendar (the Seleucid era) made its starting point the reoccupation of Babylon by Seleucus I in 312 B.C. It was adopted by the Parthian kings after their conquest of the eastern Seleucid provinces and remained in use in many other areas long after the disappearance of the Seleucid kingdom.

The history of the later Seleucids is a record of rapid decline. The children of Demetrius II Nicator and Antiochus VII Sidetes formed rival branches of the royal house between which a more or less continuous struggle was waged for control of an increasingly smaller and weaker territory. The formal end of the dynasty came with the Roman annexation of Syria in 64 B.C., but before then the last real traces of Seleucid power had been destroyed by Tigranes, the king of Armenia, in his invasion and occupation of Syria (83–69).

SELEUCUS, the name of six kings of the Seleucid dynasty (*q.v.*). The more important of these are listed below.

SELEUCUS I (surnamed for later generations NICATOR) (*c.* 358–280 B.C.), the founder of the dynasty, was the son of Antiochus, one of the generals of Philip II of Macedonia. He took part in the conquest by Alexander the Great of the Persian Empire, distinguishing himself in the Indian campaign. He did not, however, hold a leading position in the Macedonian army during Alexander's lifetime. In the arrangements made at Babylon upon Alexander's death (323) he was appointed senior lieutenant to the regent Perdiccas. During the attempted invasion of Egypt in 321, Seleucus was one of the officers who led the mutiny in which Perdiccas was murdered. In the settlement of Triparadisus in Syria (321), he was entrusted with the government of the Babylonian satrapy as a reward for his part in Perdiccas' overthrow, and in the subsequent war between Eumenes (*q.v.*) and Antigonus I (320–316) he supported the latter. Nevertheless, Antigonus regarded him with distrust, and after his final defeat of Eumenes (316), he ordered Seleucus to submit the accounts of his satrapy. Seleucus thereupon fled from Babylon and took refuge with Ptolemy in Egypt. In the war which followed between Antigonus and the other Macedonian chiefs, Seleucus played an active part as commander of naval squadrons placed under his charge by Ptolemy. The victory won by Ptolemy's army at Gaza (312) over Demetrius I (later Demetrius I Poliorcetes), the son of Antigonus, opened the way for Seleucus to return to Babylonia.

Though he brought with him only a small force of soldiers, Seleucus enjoyed the support of the Babylonian population whose favour he had won earlier in the time of his governorship. Accordingly, he successfully resisted intermittent attempts to crush him and gradually wrested the neighbouring provinces of Persis, Susiana, and Media from the nominees of Antigonus. Eventually he brought under his control the whole eastern part of Alexander's empire as far as the Jaxartes (modern Syr-Darya) and Indus rivers. But about 304 he felt obliged to make peace with the Indian king Chandragupta to whom he ceded the Indian provinces, receiving in exchange 500 war elephants. In 306, after the extinction of the old royal line of Macedonia, he had, like the other four principal Macedonian chiefs, assumed the style of king; the Seleucid era, however, which was officially regarded as the beginning of the Seleucid Empire, was dated from the time of his return to Babylon in 312. Invasions of Babylonia by Antigonus, though always ineffectual, had persisted until 302. In the campaign of Ipsus (302–301) Seleucus combined with Lysimachus to bring about the downfall of Antigonus (*see* IPSUS, BATTLE OF). A new partition of the Macedonian Empire was then made. Seleucus added to his kingdom Syria, where he founded his new capital, Antioch (*q.v.*), on the Orontes. For the eastern half of his realm Seleucia (*q.v.*) on the Tigris, another of his foundations, served as capital; there, about 293, he installed his son Antiochus as viceroy.

In the wars which followed the Battle of Ipsus, Seleucus sided at one time with Demetrius I (*q.v.*) Poliorcetes, whose daughter Stratonice he married (299 or 298); but later he joined with Lysimachus to defeat Demetrius, who became his captive in Syria (285). In the last war of his reign Seleucus defeated and killed Lysimachus at Corupedium in Lydia (281). Having occupied Asia Minor, he crossed into Europe with the intention of annexing Thrace and Macedonia. This object would certainly have been attained, for there was no one to oppose his advance, had he not been murdered by Ptolemy Ceraunus (who had earlier deserted Lysimachus in order to join him; *see* PTOLEMIES) near Lysimachia in the Thracian Chersonese (280).

In spite of his final conquests, as a result of which he came near to reuniting under himself the whole of Alexander's empire apart from Egypt, Seleucus must be reckoned, like Ptolemy I, to whom he owed a great personal obligation, as an upholder of the principle of separatism within the empire and a determined opponent of imperial unity. A fine general, he was above all a great organizer and administrator. He followed Alexander in promoting Greek and Macedonian colonization in Asia, and while he may have considered Alexander's policy of partnership between Macedonians and Persians impracticable or at least premature, he did not wholly reject it, for he was the only one of the Successors who did not repudiate after Alexander's death the Persian wife (Apama) he had taken in 324. His historical importance lies in his creation of the largest of the Hellenistic states.

SELEUCUS II CALLINICUS (*c.* 265–226 B.C.), son of Antiochus II Theos, reigned from 246. He fought against Ptolemy III of Egypt in the Third Syrian War (246–241), and in Asia Minor against his own younger brother Antiochus (*q.v.*) Hierax in a civil war which gravely weakened the Seleucid kingdom. Defeated by Hierax and the Galatians at Ancyra in Phrygia (*c.* 235), he was compelled to give up the country north of Mt. Taurus; but he struggled with some success to maintain his authority in the eastern provinces where he won a victory over the Parthians (*c.* 228).

SELEUCUS III SOTER (*c.* 245–223 B.C.), son of the above, took up the task of reconquering Asia Minor from Attalus (*q.v.*) I of Pergamum but fell by a conspiracy in his own camp.

SELEUCUS IV PHILOPATOR (*c.* 218–175 B.C.), second son of Antiochus III, succeeded his father in 187. His reign was uneventful. He was compelled by financial necessities, created in part by the heavy war indemnity exacted by Rome under the Peace of Apamea (188), to pursue an unambitious policy. Conflict with other powers was carefully avoided, everything being directed to im-

ternal consolidation and recovery. In 175 he was murdered by his minister Heliodorus, who usurped the throne. (R. H. St.)

SELF-DETERMINATION, a term widely used in contemporary international relations with a variety of meanings. Historically it meant the right of people in a state to choose their own government. In this sense it is opposed to an absolute monarchy based on the divine right of kings and is instead in accord with Rousseau's doctrine that sovereignty resides in the people and not in the ruler. The French Revolution gave currency to this idea. It was made explicit in the "Déclaration du droit des gens" that Abbé Grégoire submitted to the Convention on April 23, 1795. It declared that peoples are independent and sovereign and that every people has the right to organize and change its own government. The American Revolution provided another contribution to the doctrine of self-determination. It became the signal for similar anticolonial and independence movements in Latin America, though without the connotation of self-government. The congress of Vienna (1815) attempted to restore the old European system based on a balance of power and the principle of legitimacy. The Holy alliance of Sept. 26, 1815, was particularly concerned with the latter and did not shrink from intervention on its behalf. The Monroe Doctrine of Dec. 2, 1823, was in part at least designed to forestall any attempt at restoration of dominion over the former European possessions in the western hemisphere.

National self-determination as a political principle has evolved in the last 150 years as a by-product of the doctrine of nationalism in combination with other philosophical and political currents. Immanuel Kant's concept of the autonomy of the individual and of freedom as a condition of autonomy furnished an essential element. Johann Fichte's emphasis on the state as a condition of man's freedom and Johann Herder's idea that mankind was divided by God into different nationalities, each of which had a particular mission to fulfill, furnished the other elements. Schleiermacher, like Herder, stressed the distinctiveness of each nation based on language, character, history and culture. Nations should constitute their own sovereign state to preserve their distinctiveness and to make their preordained contribution to mankind. Mazzini argued that multinational states are artificial whereas national states are products of nature.

Nature, however, did not of and by itself produce national states. The persistent efforts of politicians acting from other motivations but drawing upon the ideological bases provided by philosophers, and the general drift of European politics resulted in a drastic redrawing of the map of Europe produced by the congress of Vienna. The Ottoman empire, a multinational and multireligious state, suffered first the impact of doctrine and politics: Greece gained independence in 1829; through the century other parts of the empire split off: Rumania, Bulgaria, Serbia. Italy was unified under the banner of nationalism and so was Germany; in the former case Napoleon III and in the latter the Prussian Chancellor Bismarck were active forces inspired by less than idealistic motives. The democratic-liberal elements looked with favour upon the spread of nationalism but, as later events showed, the new states formed on a national basis were not necessarily committed to liberal or democratic ideals or to the pursuit of peace.

World War I and the League.—In World War I the Allies, largely under the influence of Woodrow Wilson, accepted self-determination as a peace aim; the Bolshevik revolution in 1917 removed a multinational state, Russia, from their ranks and made it easier to espouse the claim of oppressed nationalities. The Bolsheviks themselves through Trotski's note to the Allied embassies in Petrograd, Nov. 21, 1917, advocated a democratic peace on the basis of "the self-determination of nations." Pope Benedict XV in his message to the heads of the belligerent governments of Aug. 1, 1917, favoured a territorial settlement taking account of the desires of the peoples. President Wilson in his address to the U.S. Senate, Jan. 22, 1917, proposed among the essential terms of peace that all nations accept the Monroe Doctrine and agree "that no nation should extend its polity over any other nation or people, but that every people should be left free to determine its own polity." In his Fourteen Points, Jan. 8, 1918, Wilson listed among the peace objectives the restoration of independence to Belgium, Rumania, Serbia and Montenegro, and of Alsace-Lorraine to France, "the freest opportunity of autonomous development" for the peoples of Austria-Hungary, and a similar opportunity for the nationalities of the Ottoman empire, and the resurrected Poland should "include the territories inhabited by indisputably Polish populations." By the time of the peace conference events had outdistanced these goals and independent states emerged in the territory of the Austro-Hungarian empire and the Ottoman empire. The principle of self-determination had to be adjusted to political exigencies and promises of territorial compensation made during the war to Italy. The principle was further compromised by strategic and economic considerations and the virtual impossibility of drawing boundaries along linguistic or ethnic lines. Some of the Ottoman provinces whose existence as independent nations was provisionally recognized in Art. 22 (4) of the covenant of the League of Nations but which were not yet ready to stand alone were placed under the mandates system (*see* MANDATE). Contrary to the assumptions of the liberal democrats, the new order based on the principle of national self-determination proved no basis for a stable peace. The principle itself became in the hands of Adolf Hitler the chief instrument for the destruction of peace.

World War II and the UN.—In World War II liberation of the territories enslaved and occupied by Germany, Italy and Japan became one of the chief peace goals of the United Nations. Self-government was envisaged for all, including those which came within the sphere of influence of the U.S.S.R., particularly Poland. Thus the Atlantic Charter of Aug. 14, 1941, declared the desire of the United Kingdom and the United States to "respect the right of all peoples to choose the form of government under which they will live." This was reaffirmed in the declaration by the United Nations of Jan. 1, 1942, and in numerous other official statements. Be it noted that self-determination here is used in the sense of self-government but because of the participation of the Soviet Union it could not necessarily mean democratic self-government nor could it mean national self-determination for all. The Baltic republics incorporated in the U.S.S.R. in 1940 were not restored to independence, though the U.S. did not recognize their annexation. In spite of the 1945 Yalta agreement (*see* WORLD WAR II CONFERENCES, ALLIED) Poland was not granted a genuine right of self-determination. Many Germans from Czechoslovakia and from territories under Soviet or Polish administration east of the Oder-Neisse line were moved to Germany.

Self-determination is affirmed in the charter of the United Nations organization. One of its major purposes is "to develop friendly relations among nations based on respect for the principle of equal rights and self-determination of peoples" as one of the measures to strengthen universal peace (Art. 1, par. 2). Another is to promote co-operation in the economic, social, cultural and humanitarian fields "with a view to the creation of conditions of stability and well-being which are necessary for peaceful and friendly relations among nations based on respect for the principle of equal rights and self-determination of peoples" (Art. 55, par. 1). In pledging themselves "to take joint and separate action in co-operation with the Organization for the achievement" (Art. 56) of those purposes the members appear to assume an obligation and thereby to elevate the principle of self-determination of peoples—neither of which is defined—from the plane of politics to the level of law. More specific obligations to develop self-government and free political institutions in nonself-governing territories and to promote self-government or independence in trust territories are assumed by the members that have responsibility for their administration (Art. 73, b, and 76, b). Moreover, the general assembly of the United Nations urged the members to speed up the process and specifically recommended that the wishes of the peoples be "ascertained through plebiscites or other recognized means" (Resolution of Dec. 16, 1952). It also recommended that "the right of peoples and nations to self-determination" be included in the projected covenant on human rights (Resolution of Feb. 5, 1952). The traditional political concept of self-determination was also declared by the assembly to apply to the economic sphere.

Responding partly to the continuous pressure of the United Nations and partly to other considerations of a political and economic

nature, western governments after the end of World War II embarked on a vast process of decolonization by divesting themselves of sovereignty over their dependencies in Asia and Africa and transferring it to the newly established states. By contrast the Soviet Union, clearly subordinating self-determination to the objective of promoting communism or socialism, in practice denied to the peoples under its sway either the right freely to elect their government or to form a state of their choice. The suppression of the Hungarian revolution in 1956 by armed intervention led to a condemnation by the United Nations (Resolution of Nov. 9, 1956) but not to a liberation of the Hungarian people. On the other hand, the Soviet Union adopted the policy of promoting self-determination and "national liberation" movements in other states provided they are deemed to offer sooner or later an opportunity for penetration by or are themselves bearers of the Communist ideology.

(L. Gs.)

SELFRIDGE, HARRY GORDON (1857?–1947), founder of a great London department store, was born at Ripon, Wis. The son of a small storekeeper, he became an errand boy at 12. At 17 he joined Field, Leiter and Co., later Marshall Field & Co., Chicago, where he worked with great success for 25 years, becoming a junior partner. After using his fortune to buy and resell profitably another store, Selfridge went to England in 1906. He began building a large store in Oxford Street, London, but his partner withdrew from the venture. He then obtained support from a wealthy tea broker and in 1908 Selfridge & Company, Ltd., was registered (with £900,000 capital) to complete the project. Covering 42,000 sq.ft. (later twice as much), the store was opened in 1909. Imaginative advertising, ingenious publicity, and novel interior arrangements made Selfridge's a household word at once. In 1937 he became a British citizen. By 1939 he had lost grip on his great enterprise and because of his personal extravagance the banks caused him to be deposed. He died at Putney, London, on May 8, 1947.

See A. H. Williams, *No Name on the Door* (1956); R. Pound, *Selfridge* (1960).

SELIGMAN, CHARLES GABRIEL (1873–1940), a pioneer in British anthropology, was born in London on Dec. 24, 1873. Educated at St. Paul's School, London, he trained in medicine at St. Thomas's Hospital and specialized for a time in pathological research. Attracted, however, by anthropology, he joined a field expedition to the Torres Strait in 1898 and another to southern New Guinea in 1904. With his wife, Brenda Z. Seligman, he studied the Veddas of Ceylon in 1907–08 and then made three ethnographic survey tours in the Sudan. This work resulted in *The Melanesians of British New Guinea* (1910), *The Races of Africa* (1930), and (jointly with his wife) *The Veddas* (1911) and *Pagan Tribes of the Nilotic Sudan* (1932). In 1910 Seligman was appointed university lecturer and in 1913 part-time professor in ethnology at the London School of Economics and Political Science. Retiring in 1934, he was given the title of emeritus professor. He became visiting professor at Yale University in 1938, and died at Oxford on Sept. 19, 1940. Seligman's anthropological interests and scholarship were very wide, in physical anthropology, archaeology, cultural anthropology, and Oriental art. He was one of the first anthropologists to study the relationship between psychoanalysis and anthropology. He received many distinctions, including fellowship of the Royal Society in 1919.

See G. H. Brown, *Lives of the Fellows of the Royal College of Physicians of London, 1826–1925* (1955). (R. F.)

SELIM I (*c.* 1470–1520), sultan of the Ottoman Empire 1512–20, known as Yavuz ("the Grim"), was a son of Sultan Bayazid II. In 1511, in order to strengthen his position in the struggle between himself and his brothers for succession to the throne, he sailed from his province of Trebizond (Trabzon) to Kaffa (Feodosiya) in the Crimea, won the aid of the khan of the Krim Tatars, and then crossed the Danube into the Balkans. Bayazid, worried over a great Shi'i revolt in Asia Minor, assigned to Selim a province in the Balkans, but Selim, fearing that the partisans of his brother Ahmed might raise that prince to the throne if their efforts to crush the Shi'i rebellion were successful, turned against his father, was defeated near Corlu in 1511, and fled for refuge to the Crimea. His brother Ahmed, finding, however, that the janizaries (*q.v.*) would not accept him as future sultan, seized much of Asia Minor. The danger that he might reach an entente with the shah of Persia led to the recall of Selim from the Crimea and to the abdication of Bayazid II in favour of Selim (April 1512). Selim overcame and killed Ahmed in 1513. He then moved against the Safavid regime in Persia, which was the source of a Shi'i religious propaganda so successful as to threaten to undermine Ottoman control over much of Asia Minor. Selim defeated Shah Ismail at Caldiran in 1514 and then, in 1515–16, subjugated the border lands between the Ottoman Empire and the Mameluke sultanate of Syria and Egypt, along the Taurus Mountains and in Kurdistan. The Mamelukes, thereupon, marched northward in 1516, only to be routed by the Ottomans at Marj Dabiq in Syria. A further campaign led to the Ottoman conquest of Egypt in 1516–17. Selim had thus, in five years of relentless warfare, solved the dangerous problems which confronted the Ottomans in the East at the close of the reign of Bayazid II. Selim I died near Corlu in September 1520, while apparently about to undertake a campaign against the Knights of St. John at Rhodes. *See* also TURKEY: *History*.

See *The New Cambridge Modern History*, vol. i, ch. xiv (1957).
(V. J. P.)

SELIM II (1524–1574), sultan of the Ottoman Empire 1566–74, was a son of Sultan Suleiman the Magnificent. During 1559–61 he was involved in a bitter conflict with his brother Bayazid over the succession to the throne. The conflict ended with the execution of Bayazid. The major event of Selim II's reign was the conquest of Cyprus, then under Venetian rule. Nicosia fell to the Ottomans in 1570 and Famagusta in 1571. Venice, meanwhile, formed an alliance with the pope and with Philip II of Spain. A joint Christian armada destroyed the Ottoman fleet at Lepanto in 1571, but the divided aims of the Christian allies prevented the exploitation of this famous victory. Venice made peace in 1573, surrendering Cyprus to the Ottomans. Don John of Austria seized Tunis in this same year, but the Ottomans, having built a new fleet since Lepanto, captured the town in 1574. Selim II died at Istanbul in December 1574. *See* also TURKEY: *History*. (V. J. P.)

SELIM III (1761–1808), sultan of the Ottoman Empire 1789–1807, was born in Istanbul on Dec. 24, 1761, the son of Sultan Mustafa III who was succeeded by his brother Abdul-Hamid I. After his father's death Selim lived in the cage-prison (*kafe*). He was well educated and, free from traditional prejudices, he maintained a secret friendship with the French ambassador and sent a representative to the French court to investigate French institutions. Thus he became familiar with Western civilization and ways of thought. When, on April 7, 1789, Selim succeeded his uncle as sultan, Turkey was at war with Russia and Austria, but he was determined to modernize his empire. After the peace of Jassy (1792) he outlined a project of reforms, the *nizam-i-jedid* ("new organization"). This was based on a scheme drawn up by his ministers, at his order, particularly on a long report on Austrian institutions prepared in Vienna by his friend Ratip Efendi. To put the plan into operation Selim created a special treasury and secured the services of European officers and experts. With their help he formed a new army modeled on Western lines; he reorganized the school of navigation; opened a new engineering school, with French a compulsory language; and introduced European military textbooks. Selim also established permanent embassies in European capitals and instructed embassy staffs to learn the language of the country to which they were accredited and send regular reports on its political, social, and cultural life. These reforms, coupled with unsuccessful wars against France and Russia, stirred up the janizaries (*q.v.*), the ulamas and the provincial governors against Selim. At one time a janizary cried out that he would rather be a Moskof (a Russian) than a *nizam* (a new-type soldier). In 1807, with the army on the Danube facing the Russians, the moment seemed favourable for

an uprising. Encouraged by some reactionary ministers, the auxiliary troops (Yamaks) on the Bosporus, who were charged with the defense of the Black Sea coast, rose in revolt. To save his throne and his life Selim abolished the *nizam-i-jedid*. Nevertheless, he was deposed on May 29, 1807, and on July 28, 1808, he was murdered in Istanbul. *See* also TURKEY: *History*.

(E. Z. K.)

SELINUS (Greek SELINOUS, modern Italian SELINUNTE), an ancient city on the south coast of Sicily, just west of modern Marinella and 8 mi. (13 km.) SE of Castelvetrano, famous for its ruined Doric temples. It was traditionally founded in 651 or in 628 B.C. (pottery finds may support the earlier date) by colonists from Megara Hyblaea and from Megara in Greece (*see* SICILY: *History*). The name, which belonged both to the city and to the river west of it (modern Modione), was derived from the wild celery (Greek *selinon*) which grows there abundantly and appears on some of its coins (*see* NUMISMATICS: *Greek Coins*). Boundary disputes with Segesta (*q.v.*) are recorded as early as 580 B.C. Selinus soon grew in importance, and its territory extended from the Mazarus (Mazaro) to the Halycus (Platani) river. About 510 Peithagoras, and after him the Spartan refugee Euryleon, set themselves up as tyrants. Selinus was on the Carthaginian side when the Carthaginians were defeated at Himera (*q.v.*) in 480. Thucydides speaks of the treasures in Selinus' temples, and the city had a treasury of its own at Olympia. A dispute between Selinus and Segesta was one of the causes of the Athenian expedition to Sicily of 415 B.C. After its failure (413) the Segestaeans appealed to Carthage, and an overwhelming force under Hannibal, son of Gisgo, took and destroyed Selinus in 409; the walls were razed and only 2,600 inhabitants escaped to Acragas (Agrigento). In 408 Hermocrates (*q.v.*) occupied Selinus and rebuilt the walls, but he fell in an attempt to enter Syracuse, and as a result of the treaty of 405 Selinus became subject to Carthage and remained so with brief interruptions until its inhabitants were transferred to Lilybaeum (Marsala; 250 B.C.). It was never afterward rebuilt and the temples were all toppled, probably by an earthquake; several fallen columns have been reerected in modern times.

The ancient city occupied a sand hill running north and south; the southern part (overlooking the sea), which was the acropolis, is surrounded by fine masonry walls of rectangular stone blocks, which show traces of the reconstruction of 408 B.C. Two main streets run north and south and east and west, with others diverging at right angles.

The southeast corner contains several temples. The deities to whom they were dedicated are not in every case known, and they are conventionally known by letters. In all the large temples the cella is divided into two parts, the smaller and inner of which (the *adytum*) was intended for the cult image. There are traces of early temples on the acropolis, but the earliest and largest extant is C (mid-6th century; 209 × 78 ft.). It had 6 columns (the usual number) at each end (a double row in the front) and 17 on each side. From it came three archaic metopes in the National Archaeological Museum, Palermo. Some of its coloured terra-cotta decorations have also been discovered, including the fragments of an enormous Gorgon mask, over 8 ft. high, from the centre of one of its pediments. In front of it stood a large altar more than 60 ft. long. Next to it on the north lies temple D (late 6th century; 183 × 77 ft.), both having been included in one precinct with other buildings of less importance; immediately to the east of D is a large altar. B is a small late temple; A and O (early 5th century; both about 132 × 53 ft.) lie on the south side of the main east-west street in another precinct.

At the north end of the acropolis are extensive remains of the fortifications of Hermocrates, built across the narrow neck connecting the acropolis with the rest of the hill. In front of the wall lies a deep trench, and outside this a projecting semicircular bastion commands the entrance on the east, a winding trench approached by a pair of double gateways. The builders reused fragments from earlier buildings, mostly private houses, but including a small temple; fragments of four metopes from this temple (early 6th century) are at Palermo.

Outside the ancient city, on the west of the Selinus River at Gaggera, lie the ruins of a temple of Demeter Malophoros, with a propylon (monumental entrance) leading to the sacred enclosure. The temple itself (the third on the site) has a cella with a narrow door and no columns; outside and in front of it was a large altar 52 ft. long. A large number of offerings were excavated, including strange double-headed steles dedicated to Zeus Meilichios. The earliest temple must have been built soon after the foundation of the city, the latest shortly after 600 B.C. The propylon may date from after 409 B.C.

On the hill east of Selinus, separated from it by the flat Gorgo di Cottone, lie three huge temples. No other remains have been found around them; it is likely that they were outside the town but stood in a sacred enclosure. A peculiarity of the construction of the oldest temple, F (or S; late 6th century; 203 × 80 ft.), is that the outside columns were linked together by stone screens over 10 ft. high, possibly to keep the ceremonies secret. The huge temple G (or T; begun late 6th century but worked on well into the 5th; 361 × 164 ft.) was dedicated to Apollo; though it was never completed (many of the columns still remain unfluted), it was in use. Its plan is curious; it has 8 columns at each end and 17 along each side, and two lines of 10 small columns, probably in more than one story, divide the cella lengthwise. The blocks of stone were quarried from the Cave di Cusa, 8 mi. to the northwest, where similar blocks intended for it may still be seen. The third temple, E (or R; early 5th century; 222 × 83 ft.), was apparently dedicated to Hera. Its fine metopes are now at Palermo. The cemeteries outside the city on all three sides provided valuable material for dating.

SELJUKS, the name of the ruling family of the Oghuz (Ghuzz) Turkmen tribes who invaded western Asia in the 11th century and founded a powerful empire, later to be divided into the principalities of Iran, Syria, and Asia Minor. The history of these invaders forms the first part of the history of the Turks in the Near and Middle East.

During the 10th century, in the course of the migrations and struggles of the Turkish peoples of central Asia and southeast Russia, a group of nomadic Turks under a chief named Seljuk settled in the lower reaches of the Syr-Darya River, and later embraced Islam. They were incorporated in the frontier defense forces of the Samanids (*q.v.*) and moved to the vicinity of Bukhara *c.* A.D. 985. After the fall of the Samanids, they were established by Mahmud (*q.v.*) of Ghazni in the border regions of Khurasan, but it was difficult to induce warlike nomads to live peacefully within a settled empire. While Mahmud's son Mas'ud was busy waging war in northern India the two grandsons of Seljuk, Chagri (Chaghri) Beg and Togrul (Tughril) Beg, saw the chance to win a realm of their own with the support of Persian nobles and religious leaders who were anxious to meet the threatening progress of heretic Shi'ite sects reinforced by the Buyid princes of western Iran and Iraq and the Fatimid Isma'ilian caliphate of Egypt. When Mas'ud saw the danger, it was too late: he was utterly defeated at Dendenkan (Dandanqan) near Merv in 1040. Thereafter Chagri Beg remained in control of the greater part of Khurasan while Togrul, with a mixed army of Turkmen and regular Mameluke (slave) troops, set out to conquer new territories in the west.

The Great Seljuks.—For the details of the reigns of the first three Seljuk sovereigns, known as the Great Seljuks, reference should be made to the articles TOGRUL BEG; ALP ARSLAN, MOHAMMED IBN DA'UD; and MALIK SHAH. Suffice it here to say that Togrul Beg, a strong leader of men and a clear-headed statesman, achieved the creation of an empire which at his death (1063) included central and western Iran and Mesopotamia with Baghdad itself. There the caliph al-Ka'im welcomed him in 1055 as his deliverer from the rule of the Buyids and bestowed on him the title of sultan with the task of restoring the unity of the Muslim world under the religious sway of the Abbasid caliphate. Alp Arslan (1063–1072 or 1073), who succeeded both Chagri and Togrul, and Malik Shah completed his conquering work. When

Malik Shah died in 1092, the Seljuk Empire included the whole of Iran with the exception of the Ghaznavid realm of the Indian borderland, the whole of Mesopotamia, and Syria, including Palestine, to the frontier of Egypt. Furthermore, other Turkmen invaders closely akin to the Seljuks had occupied the Asiatic provinces of the Byzantine Empire up to the Aegean Sea. The organization of the empire was the task of the famous vizier Nizam al-Mulk (*q.v.*), who remained in power during the reigns of both Alp Arslan and Malik Shah.

The main problem facing the Seljuks was to persuade the Turkmen invaders, to whom they owed their victory, to live within the framework of the bureaucratic Iranian-Iraqi state. This problem was never completely solved. The Turkmen tribesmen had no interest in victory over heretics if their lands were unsuitable for stockbreeding or if pillage was not allowed; but on the northwestern frontier of Iran lay the Byzantine Empire, including half of Armenia, which was lacking religio-national homogeneity and the kind of military force able to fight against nomadic invaders. Love of plunder and zeal for a holy war drew the Turkmens into Byzantine territory, and, to prevent them from becoming quite estranged from him, the sultan had sometimes to lead them himself. Thus Alp Arslan won immortal fame in the Muslim world when he defeated a huge Byzantine army at Manzikert in 1071, capturing the Byzantine emperor Romanus IV Diogenes. Thenceforth the Turkmens were able to settle in Asia Minor undisturbed.

The main feature of the Seljuk Empire was its religio-political character. The regime had to fight not only external wars but also wars against heretics within its frontiers, and to the Seljuks Islam owes much of its later achievements. Before the Seljuk period education in the Muslim world had not been organized by the state. Now madrasahs (colleges) were founded, with the object of training administrators and the upper classes in Islamic science. The head of orthodox Islam was the Abbasid caliph, but, though he was permitted a degree of veneration and independence in Baghdad, he had no real political power in the empire. The sultans as well as the caliph considered it their duty to promote religious works; for this reason as well as to show their power they built many mosques, including the glorious mosque of Isfahan.

Strange as it may seem, the rule of the Turkish Seljuks fostered rather than hampered the progress of Persian cultural autonomy. Before the Seljuk era a new form of Persian literature had developed in the Samanid territories of northeastern Iran and Transoxiana. This was no longer written in the pure old language or in the alphabet of pre-Islamic Iran, but in the Arabic script, with a number of borrowed Arabic words. At the same time the Buyids had favoured a form of Persian patriotism which expressed itself in Arabic. Seljuk rule, on the other hand, led to the spread of literary Persian to the whole of Iran. The Turks had no cultural Islamic tradition and almost no written literature. As the Iranians had been their instructors in Islam, they knew no cultural language other than Persian and showed no interest in the achievements of scholars or poets writing in Arabic. From the time of the Seljuks onward, the Arabic language disappeared from the Iranian lands.

It is wrong to believe, as many have believed, that the pursuance of an Islamic policy and of conquest in Asia Minor led the Seljuks to persecute the Christians. The plundering of the Turkmen armies in the Byzantine Empire no doubt caused much suffering and loss to Eastern Christianity, but inside the Seljuk Empire, as soon as order was restored, the lot of Christians was much the same as it had been before: the crusaders, who thought it must be otherwise, were judging conditions in Jerusalem by those prevailing in Asia Minor.

The Later Seljuks.—Despite its successes there were weaknesses in the Seljuk Empire. It could not prevent the growth of the new terrorist sect, the Assassins (*q.v.*), which was to inspire such dread in the medieval East and which began its activities with the murder of Nizam al-Mulk (1092). Furthermore the Seljuks, like the Buyids before them, could not rid themselves of the idea that sovereignty belonged to a family rather than to a single man; thus even the most powerful sultans thought it necessary to give provinces as appanages to their relatives. In the early years of the Seljuk conquests a practically independent principality had been founded in Kerman by a son of Chagri Beg, Qavurt, who extended his conquests to Oman on the Persian Gulf. Another independent but short-lived principality was created in Syria, partly for military reasons, by Malik Shah in favour of his brother Tutush.

When Malik Shah died, leaving several sons by different wives, all of them very young, the quarrels between them and their supporters resulted in a partition of the Seljuk heritage among Barkiyarok, the eldest son; his brother Mohammed, who received northwestern Iran; and a third brother, Sanjar (*q.v.*), who was given charge of Khurasan. When Barkiyarok died in 1104 Mohammed was able to establish only a measure of control in central and western Iran, and this broke down at his death (1118). Sanjar's realm in Khurasan, however, attained a new power and glory, which were magnified in the eyes of posterity by the length of his reign and the disasters which befell him in his last years. It is necessary here only to recall his victories over the rival Turkish kingdom of the Qarakhanids in Transoxiana and over the Ghaznavids of the Indian borderland. This was followed by his defeat in 1138 by new invaders from central Asia, the Khara-Khitai, and by the revolt of his vassal in Khwarizm (Khorezmia). Finally came the general uprising of the Ghuzz (1153), which resulted in Sanjar's captivity, from which he escaped only to die in 1157. Years of disorder and misery ensued for Khurasan, until its final incorporation in a new Khorezmian empire in the reign of Takash (1172–99).

Thereafter no territory was left in the former Seljuk Empire where a sultan could enjoy real power. When pretenders quarreled they sought the help of high military officers, to whom they were obliged to abandon the government of whole provinces. This was especially so in the case of the atabegs, officers who were entrusted with a kind of tutorship over minor princes. Tribal chiefs also profited by the disorders to make themselves independent, and the caliph himself thought the time ripe, if not to recover the ancient power of the Abbasids over the whole of the Muslim world, at least to secure a principality of his own in Iraq.

The first of the Seljuk lines to disappear was that in Syria. There Tutush's sons, Ridwan of Aleppo and Duqaq of Damascus, had quarreled and were weakened by the attacks of the crusaders. Toghtekin, son of Buri, the atabeg of Duqaq, founded a dynasty of his own (the Burids) when his master died in 1104. In Aleppo the general feeling was against "Easterners," and the dynasty scarcely survived Ridwan's death (1113). Atabegs were also governing upper Mesopotamia around Mosul, and one of them, Zangi, united this province and Aleppo under his sway in 1128, thus creating a new dynasty there. Another atabeg dynasty, which was to last until the beginning of the 13th century, came to power somewhat later in Azerbaijan. These atabegs "protected" the last Seljuks of the Iranian line, who resided in Hamadan but had no powers except those granted them by their all-powerful tutors.

In the mid-12th century, the caliph again became independent, and when the last of the Iranian Seljuks, Togrul, tried to recover some of his lost influence, the caliph appealed to the shah of Khorezmia (the Khwarizm-shah) for help. As a result Togrul died on the battlefield in 1194. Meanwhile other parts of the Seljuk heritage had met their fate at the hands of tribal chiefs. Even Arab tribes, such as the Mazyadits on the Iraqi borders, had taken advantage of the situation to win at least temporary autonomy. The principality of Kerman did not long survive the death (1170) of its sultan Togrul. His sons quarreled and called in foreign aid, with the result that the country was utterly devastated and fell an easy prey to a band of Ghuzz from Khurasan under their chief, Malik Dinar (1185). Ten years later it was incorporated in the Khorezmian empire. Only in Asia Minor did Seljuk power survive, and there it did not reach its peak until the 13th century.

The Sultanate of Rum.—The invasion of Asia Minor began as an uncoordinated movement of Turkmen tribesmen from Azerbaijan, and the expeditions of Togrul Beg and Alp Arslan were aimed as much at controlling the tribesmen as at conquest. Alp Arslan's victory at Manzikert (1071) destroyed the Byzantine

frontier organization and enabled the Ghuzz to establish themselves in Byzantine territory, where they engaged as mercenaries in the struggles between the local commanders. Among a host of tribal chiefs the leading place was taken about 1075 by the sons of Togrul Beg's cousin Kutalmish (Kutlumush), who were violently hostile to Malik Shah. During the struggles of rival generals for the throne of Constantinople (1078–81), one after another of the contestants called for aid from the sons of Kutalmish and opened to them the gates of their cities, including Nicaea and Nicomedia (Izmit). By 1080 Suleiman ibn Kutalmish held the greater part of Asia Minor as the ally of the emperor and rival sultan to Malik Shah. In 1084 Antioch (Antakya) was surrendered to him, but in 1086 he was killed near Aleppo in battle with Tutush and a coalition of Syrian princes. Malik Shah attempted to take advantage of Suleiman's death, both by proposals for an alliance with the Byzantine emperor Alexius I Comnenus and by military expeditions into western Anatolia, but with little success; and on his death (1092) Suleiman's son Kilij Arslan (who had been captured by Malik Shah at Antioch), escaping from his captivity, reconstituted the sultanate. In the interval, however, northeastern Anatolia had been occupied by a rival Turkmen chief, Danishmend of Sivas, whose successors engaged in a prolonged conflict with the Seljuk sultans.

The new sultan was immediately confronted with the First Crusade. The first crusader bands, under Walter the Penniless, were defeated at Nicaea (1096), but the Turks were severely defeated before Nicaea and at Dorylaeum (Eskisehir) in 1097 and driven into the interior, while the emperor Alexius reoccupied western Anatolia. After his victory over the next wave of crusaders (1101), Kilij Arslan, tempted by the disorders which had weakened the Seljuks in Iraq, made a bid for the greater sultanate. He succeeded in capturing Mosul but was defeated by the forces of his kinsman of Aleppo and drowned in the Khabur (Habur) River (1107).

This event proved decisive in determining the future development of the sultanate of Rum (the name used by the Turks for the Byzantine empire; *see* RUM). The Seljuks, hemmed in between the Greeks and the crusading states in Syria and increasingly isolated from the east, gradually established an organized and settled Anatolian kingdom. Kilij Arslan was succeeded by his son Malik Shah (1107–16), and he by his brother Mas'ud I (1116–55), who established his capital at Konya (Iconium). Mas'ud's long reign was occupied by resistance to the encroachments of the Greeks and by engagements and negotiations with the Danishmends, the crusaders, and his Muslim neighbours. During the reign of his son and successor, Kilij Arslan II (1155–92), the Armenians established a principality in Cilicia, but the Danishmends were finally subdued and their territories annexed to the sultanate.

Kilij Arslan's numerous sons, each of whom held the command of a city of the empire, embittered his old age by their mutual rivalry, and the eldest, Qutb ud-din, tyrannized over him in his own capital, exactly at the time that Frederick I Barbarossa entered the sultan's dominions on his way to the Holy Sepulchre (1190). Konya itself was taken and the sultan was forced to provide guides and provisions for the crusaders. Kilij Arslan lived two years longer, finally under the protection of his youngest son, Kaikhosrau, who held the capital after him till 1196 when his elder brother, Rukn al-din Suleiman, having vanquished his other brothers, ascended the throne and obliged Kaikhosrau to seek refuge at the Greek emperor's court. Rukn al-din, who died in 1204, saved the sultanate from destruction and conquered Erzurum, which had been ruled for a considerable time by a separate dynasty; but Rukn al-din's son, Kilij Arslan III, was soon deposed, with Greek assistance, by Kaikhosrau.

After the establishment of the Latin empire of Constantinople (1204) the Turks were the natural allies of the Greeks and the enemies of the crusaders and their allies, the Armenians. Kaikhosrau, therefore, in 1207 took the important harbour of Attalia (Antalya) from the Italian Aldobrandini; but in 1211 he perished in battle with Theodore I Lascaris, emperor of Nicaea. His son and successor, Kaikaus, made peace with Lascaris and extended his frontiers to the Black Sea by the conquest of Sinope (Sinop; 1214). On this occasion he took prisoner the Comnenian prince Alexius, who ruled the independent empire of Trebizond (Trabzon), and compelled him to acknowledge the supremacy of the Seljuks, to pay tribute, and to serve in the armies of the sultan. Elated by this great success and by his victories over the Armenians in Cilicia, Kaikaus attempted the capture of Aleppo, at this time governed by the descendants of Saladin, but the project was defeated by Ayyubid resistance.

Kaikaus' brother, Ala al-din Kaikobad I (1219–37), was the most powerful and illustrious prince of this branch of the Seljuks. He extended his rule as far as Seleucia and desisted from further conquest only on condition that the Armenian princes would enter into the same kind of relation to the Seljuks as had been imposed on the Comnenians of Trebizond. But his greatest military fame was won by a war which, however glorious, was to prove fatal to the Seljuk Empire in the future; in conjunction with his ally, the Ayyubid prince Ashraf, he defeated the Khorezmshah, Jalal al-din, near Erzincan (1230). During this war Kaikobad put an end to a collateral dynasty of the Seljuks of Erzurum and annexed its possessions. He also gained the city of Khilat with dependencies which had recently been taken from the Ayyubids by Jalal al-din. This acquisition, however, led to a new war, as Kaikobad's ally, the Ayyubid prince, contested it. Sixteen Muslim princes, mostly Ayyubids, of Syria and Mesopotamia, under the leadership of Malik al-Kamil, prince of Egypt, marched with considerable forces into Asia Minor against him. Happily for Kaikobad, the other princes mistrusted the power of the Egyptian, and it proved a difficult task to penetrate through the mountainous, well-fortified accesses to the interior of Asia Minor. The advantage thus rested with Kaikobad, who extended his power in upper Mesopotamia. This expansion was pursued by his son Kaikhosrau II.

The Seljuk sultanate of Asia Minor can now be seen to have been one of the most important Muslim states of its age. Its population was a mixed one, including Christians, Armenians, Greeks, Syrians, and Iranian Muslims; but, when compared with the other Seljuk realms, of which the Turks had been only a small, if leading element, it was really "Turkey" and was so called by its contemporaries. The Seljuks of this line succeeded in establishing an administration largely based on the institutions of their Iranian-Seljuk neighbours, but it was modified by the Byzantine heritage and by its own evolution. With order and tolerance of all races and religions established, agriculture and mining activity revived, so that to foreigners Turkey seemed one of the richest of countries; meanwhile commerce was developed with the assistance of Italian merchants. In the cities beautiful buildings, several of which still survive, show the purity of an art related to, though not exactly identical with, the Iranian-Seljuk art of the same period. Literature, mostly in Persian, flourished, and, with it, mystical movements, such as that inspired by Jalal-ud-din Rumi (*q.v.*).

Yet this political organization and civilization were not really soundly based. The Seljuks failed to tame the Turkmens, particularly in the frontier districts, who, though partially settled, were impatient of centralized administration; they remained fond of petty wars against their Christian neighbours and still adhered to their traditional social and religious beliefs and practices. Newcomers from the countries invaded by the Khorezmians and Mongols added to their feeling of unrest. This helps to explain why, when the Mongol flood reached the frontiers of Turkey, which were no longer protected by the Khorezmian state, the Seljuk realm was no more able to resist than had been the Muslim principalities of Iran. At the Battle of Kosehdagh (1243), between Erzincan and Sivas, the independence of the Seljuks was lost forever.

The Mongol Protectorate.—The Mongols did not destroy the Seljuk state, but, in accordance with their plan, reduced it to vassalage. After the death of Kaikhosrau II (1245) the quarrels between his sons led to a division of Asia Minor, Izz al-din Kaikaus II taking the part west of the Halys and Rukn al-din Qilij Arslan IV the part to the east. When the former intrigued with the Mamelukes of Egypt and the Byzantine emperor, however, he was driven out and fled to Constantinople. The unity of the realm was thus restored, but the financial requirements of the

Mongols and the intrigues of the great chiefs with them against one another quickly brought about a breakdown of the Seljuk administrative system. In the central provinces and cities, the all-powerful minister, the *perwane* Mu'in al-din Suleiman, who in 1267 had Rukn al-din executed, succeeded in maintaining the Iranian-Islamic civilization of the recent golden age; to this end he co-operated with the Muslim viziers of the Mongol Il-khan of Iran, the suzerain of Asia Minor. In the distant and mountainous districts, however, the Turkmen amirs, free from any form of government, established small principalities of their own: in the Taurus; on the Byzantine frontier; on the south Aegean coast; later even near the Straits and the Black Sea. With their help and that of Baybars, the powerful Mameluke sultan of Egypt, the most dreaded enemy of the Mongols, a group of Muslim nobles in Asia Minor revolted during 1276–77 against the Mongol protectorate. The *perwane* himself had negotiated with them and although he finally refused to join them, thus assuring the victory of the Mongols, he was executed. For a time the Seljuk sultanate was then no more than a Mongol province. Seljuk sultans, Kaikhosrau III (d. 1283), Mas'ud, and Faramarz, still reigned nominally, but in the first years of the following century the dynasty ended in obscurity.

Thereafter the power of the Turkish amirates increased and the control of the Mongol Il-khans of Iran became less effective until it also finally disappeared, in the 1330s. For later Turkish history *see* TURKEY.

BIBLIOGRAPHY.—No adequate general studies of the Seljuks exist, and the only important Oriental works to have been translated into a Western language are that of Nizām al-Mulk, Eng. trans. by H. Darke, *The Book of Government* (1960), and the chronicle of Ibn al-Bībī, German trans. by H. W. Duda, *Die Seltschukengeschichte des Ibn Bibi* (1959). Original works in Western languages include: three chapters by Claude Cahen in the *History of the Crusades*, ed. by K. M. Setton, vol. i (1955) and vol. ii (1962), where references will be found to other studies; P. Wittek, "Deux Chapitres de l'histoire des Turcs de Roum," in *Byzantion*, vol. xi (1936); W. Barthold, *Turkestan Down to the Mongol Invasion*, Eng. trans. by H. A. R. Gibb (1928, reprinted 1958); and M. F. Sanaullah, *The Decline of the Seljuk Empire* (1938). (H. A. R. G.; CL. CA.)

SELKIRK (SELCRAIG), **ALEXANDER** (1676–1721), Scottish sailor who was the prototype of Robinson Crusoe, was born at Largo, Fife, the son of a shoemaker. In 1695 he ran away to sea to join the buccaneers and by 1703, under the surname of Selkirk, he was sailing master in the galley "Cinque Ports," the consort of the "St. George," captained by William Dampier, on a privateering expedition in the Pacific. In September 1704, after a quarrel with his captain, Thomas Stradling, Selkirk was put ashore at his own request on the uninhabited island of Juan Fernández, west of Valparaíso, Chile. He remained there alone until Feb. 1, 1709, when he was discovered by Capt. Woodes Rogers in the "Duke," whose pilot was Dampier. Selkirk finally sailed from the island on Feb. 13. He was appointed mate to Rogers and in March was given command of a captured prize ship, the "Increase." He returned to England in October 1711 and met the essayist, Richard Steele, who wrote up his story in *The Englishman* (No. 26; Dec. 3, 1713). In 1719, a year after the publication of the second edition of Rogers' narrative of his voyage, Daniel Defoe made use of his story in *Robinson Crusoe*. Selkirk returned in 1712 to Largo, where he lived like a recluse, and later went to sea again. He died in 1721 when he was master's mate of HMS "Weymouth." A pamphlet, *Providence Displayed*, purporting to be by Selkirk, is a forgery.

SELKIRK, THOMAS DOUGLAS, 5TH EARL OF (1771–1820), Scottish philanthropist who founded the Red River Settlement in Canada, was born at St. Mary's Isle, Kirkcudbrightshire, on June 20, 1771. He succeeded his father, Dunbar Douglas, in 1799. A Whig in politics, he believed that the hardships of the peasantry in the Scottish Highlands could only be alleviated by emigration. He went to Canada in 1803 and established a large settlement on Prince Edward Island. In 1810 he acquired control of the Hudson's Bay Company, which granted him (May 1811) a vast tract of land in the Red River Valley, near present-day Winnipeg, where he founded a settlement. However, the hostility of the North-West Fur Company seriously impeded the colony (*see* RED RIVER SETTLEMENT). Selkirk returned in January 1818 to Upper Canada where, after lengthy legal actions, his rivals won heavy damages against him. Broken in health and having lost a fortune, he returned to England in November 1818. He died at Pau, in France, on April 8, 1820. Selkirk laid the foundations of Winnipeg and Manitoba, where the town of Selkirk commemorates his name.

SELKIRK, a southern county of Scotland, bounded north and west by the county of Peebles, north by Midlothian, east and southeast by Roxburgh, and south and southwest by Dumfries. Area 268 sq.mi. (693 sq.km.).

Physical Geography.—Forming a rectangle 25 mi. by about 12 mi. (40 km. by about 19 km.) it lies southwest–northeast, and this trend echoes that of the three main rivers, Yarrow, Ettrick, and Ale, the first two joining above Selkirk and flowing to the Tweed which runs for some 10 mi. (16 km.) across the north of the county. Underlain throughout by folded Silurian grits and shales, the physical divisions are largely a function of differential erosion. The west and southwest comprise the highest land, much of it a rolling erosion surface at 1,800–2,000 ft. (550–600 m.), above which rise Broad Law (2,755 ft. [840 m.]) and Ettrick Pen (2,270 ft. [692 m.]) on the Peebles and Dumfries boundaries respectively. The deep trenches cut by the Megget Water and by the Yarrow and Moffat Waters open routes and provide farmland in this area of nardus grass sheep country, where precipitation is over 60 in. (1,524 mm.) and snow may lie for 60 days in the year. As it was once a local centre for ice dispersal there is much bare rock and thin podsolized soils, and glacial drift occurs only in the valleys. The beauty of the Vale of Yarrow inspired Sir Walter Scott and William Wordsworth. Eastward the rocks are less resistant and the landscape consequently softens, smaller remnants of the higher plateau surfaces remain, valley slopes are gentler, and there is more improved land, although the flat floors at about 600 ft. (180 m.) are liable to flooding. St. Mary's Loch (3 mi. [4.8 km.] long), separated by a narrow isthmus from the Loch of the Lowes (1 mi. long), lies in this belt. The eastern third of the county is the lowest. The Ale Water is entrenched in a surface at about 1,200 ft. (370 m.) along the Roxburgh border, with hills seldom above 1,600 ft. Ice action has molded the landscape into "swarms" of drumlins (*see* GLACIER) 100–300 yd. (90–275 m.) long and 30–50 yd. wide, lapped by peat bogs and lochans formed on thick deposits of glacial drift. The heart of the county lies in the north around the town of Selkirk, where the valleys widen and coalesce with Tweedside itself; precipitation is about 35 in. (889 mm.) and there is much glacial drift, so a farming landscape predominates. (A. M. LE.)

Bird and animal life include pheasant, grouse, partridge and duck, roe deer, and foxes. The rivers are noted for their trout and salmon.

History.—The site of a Roman camp has been confirmed near Oakwood, in the Ettrick Valley; but the natives were probably held in check from the station at Newstead near the Eildons. Of the few so-called British camps situated in the lower valleys the most important is the large work on Rink Hill in the parish of Galashiels. At Torwoodlee, 2 mi. (3.2 km.) NW of Galashiels, are the ruins of the only example of a broch (round tower) in the Border counties; some Roman remains were found there. An ancient earthwork of uncertain origin runs 4¼ mi. from Linglie Hill near Philiphaugh, northwest of Selkirk burgh, to Mossilee near Galashiels. It consists of a ditch, about 30 ft. wide and 3 ft. deep, and a bank made by the excavated earth, thrown out usually on its lower side. The history of the shire for six centuries following the retreat of the Romans is that of the whole of southeastern Scotland. The county formed part, first, of the British kingdom of Strathclyde, then of the Saxon kingdom of Northumbria, and finally, about 1020, was annexed to Scotland.

To the north of Hangingshaw, in the country between the Yarrow and Tweed, Sir William Wallace constructed an earthwork in 1297, still called Wallace's Trench, 1,000 ft. (300 m.) long and

terminating on the top of a hill in a large square enclosure. There he lay till his plans were completed, and at last departed, his forces including a body of Selkirk archers, for a raid into the north of England. During the prolonged strife that followed the death of Robert I, the Bruce (1329), the foresters were constantly fighting, and the county suffered more heavily at Flodden (1513) than any other district. The lawlessness of the Borderers was at length put down by James V with a strong hand. He parceled out the forest in districts and to each appointed a keeper to enforce order and protect property. The county was known at that time as Ettrick Forest and was a hunting ground for the Scottish kings. In 1529 the ringleaders of the Borderers, including William Cockburn of Henderland, Adam Scott of Tushielaw, and the notorious Johnnie Armstrong, were arrested and promptly executed. This severity had the desired effect, though in 1603 the freebooters and moss-troopers again threatened to be troublesome, until James VI's lieutenants ruthlessly stamped out disaffection. The Covenanters held many conventicles in the uplands, and their general, David Leslie (later Lord Newark), routed the marquess of Montrose at Philiphaugh in 1645.

Sir Walter Scott (*q.v.*) was sheriff of the county from 1799 until his death, and from 1804 to 1812 he lived in the mansion of Ashiestiel, on the south bank of the Tweed.

Population and Administration.—The population of the county in 1961 was 21,052, of whom only 46 could speak both Gaelic and English. Selkirk (*q.v.*) is the county town and only royal burgh (pop. 1961, 5,634), with a charter dating from 1535, but Galashiels (*q.v.*), the only other small burgh, is the biggest town (pop. 1961, 12,373). There are two county districts. The rural population is on the decline.

The county, along with the counties of Roxburgh and Peebles, sends one member to Parliament. It forms part of the sheriffdom of Roxburgh, Berwick, and Selkirk with a court in Selkirk.

Agriculture and Industry.—The hill land is divided into large farms of 1,000–3,000 ac. (400–1,200 ha.) carrying sheep and hill cattle, the sheep being mainly Black-face Highland and Cheviot, and the cattle Galloway or other hardy breeds. Arable land is largely used to produce fodder for stock, principally oats and turnips, with some barley. The numbers of hill cattle have markedly increased since 1946. The predominant industry in the towns is the woolen industry (tweeds, hosiery, and yarn), and there is a large tannery in Galashiels. (W. T. D.)

See D. L. Linton and C. P. Snodgrass, ***Peebles and Selkirk***, Land of Britain Series, no. 24, 25 (1946).

SELKIRK, a royal and small burgh and the county town of Selkirk, Scot. Pop. (1961) 5,634. It lies on a hillside at the eastern edge of Ettrick Forest and on the right bank of Ettrick Water, 39 mi. SSE of Edinburgh by road. There are statues of Sir Walter Scott in his sheriff's robes (he was sheriff 1799–1832) and of Mungo Park, the African explorer, who was educated at the grammar school; and there is a memorial of Flodden Field, where 80 townsmen fought and fell.

As its early name (*Scheleschyrche*) indicates, Selkirk originally consisted of a number of *shiels* (huts) in the forest beside which a church had been built by the Culdees of Old Melrose. David I, while prince of Cumbria, founded in the early 12th century a Benedictine abbey, which was removed in 1147–52 to Kelso. He also built a castle which was captured by Edward I, by whom it was enlarged and strengthened. It was retaken by William Wallace in 1297, from which time it remained in the hands of the Scots till the Battle of Halidon Hill (1333), when it was delivered to the English. It was probably destroyed in 1417 when Sir Robert Umfraville, governor of Berwick, set fire to the town. Nothing remains of the castle save some green mounds at Haining. The burgh charter granted by David I was renewed by James V in 1535. From an early period shoemaking has been the staple industry and the inhabitants have been known as souters (shoemakers). Though this craft has given way to tweed manufacture, the tradition of the shoemakers is still upheld when someone is made a "Souter" on receiving the freedom of the burgh, for he then has to "lick the birse." This entails drawing a small shoemaker's brush of mild boar's bristles, steeped in wine, between his lips. In memory of Flodden, the Common Riding takes place each June, when the bounds are ridden by a cavalcade of horsemen; at the end of the ride the standard-bearers cast their colours to the strains of Selkirk's lament, "The Flowers of the Forest."

SELKIRK MOUNTAINS, in southeastern British Columbia, Can., extend for about 200 mi. (322 km.) N from the United States border and, with the Purcell Mountains to the east, lie between it and the northern bend of the Columbia River. Selkirk, Purcell, Monashee, and Cariboo mountains form major subdivisions of the Columbia Mountains, a great wedge of rugged terrain lying west of the Rocky Mountain Trench and south and east of the Fraser River.

Lowest in the south where their summits average about 7,500 ft. (2,286 m.), the Selkirk Mountains increase in elevation northward, several peaks attaining heights of over 10,000 ft. toward their northern extremity. The highest peak, Mt. Sir Sandford, stands at 11,590 ft. In many places the mountains rise abruptly to over 8,000 ft. above adjacent valley floors, affording wild and magnificent scenery. Extensive glaciers and snowfields are found in Glacier National Park, in the north; perhaps the most celebrated is the Illecillewaet, near Glacier, on the Canadian Pacific Railway. The Selkirks are crossed by railway and highway at Rogers Pass, discovered in 1883. The engineering difficulties to be overcome included the building of five-mile-long Connaught Tunnel, east of Glacier. (A. L. Fy.)

SELLA, QUINTINO (1827–1884), Italian statesman who not only put the government's finances on a sound footing but also played a decisive role in the annexation of Rome. He was born at Mosso, near Biella, in Piedmont, on July 7, 1827. After studying engineering at Turin and in Paris, he obtained an academic post at Turin, and traveled widely in the course of his research. In 1860 he was elected to the Sardinian–Piedmontese Chamber of Deputies.

In March 1862 Sella was appointed minister of finance in Urbano Rattazzi's government for the new Italy; but this government fell in December. When he became minister of finance again in A. F. La Marmora's cabinet in September 1864, he dealt energetically with the deficit of 200,000,000 lire then existing, but was again forced to resign in January 1866. The grist (or corn milling) tax, which he had proposed in 1865, was adopted by L. F. Menabrea's government in 1868; and in December 1869 Sella became minister of finance for the third time, in a cabinet formed by himself but with Giovanni Lanza as prime minister. The grist tax and Sella's other fiscal expedients over the next three years restored the national finances. In 1870, during the Franco-German War, it was Sella who prevailed on Victor Emmanuel II to take advantage of France's predicament in order to occupy Rome (*see* ITALY: *History*).

The Lanza-Sella government fell in June 1873. Having retired from politics in 1881, Sella died at Biella on March 14, 1884. His *Discorsi parlamentari* fill five volumes (1887–90).

SELMA, a city of Alabama, U.S., the seat of Dallas County, is located on the north bank of the Alabama River, 50 mi. W of Montgomery. It is in an area of rich soil suitable for cotton, livestock, pecans, and diversified farm products, all of which are produced in abundance. The city is a lumber and manufacturing centre; products include cotton bags and yarn, clothing, food products, cigars, toys, and fertilizers. Craig Air Force Base is located nearby. The city is also noted as a medical centre. In 1965 it was the centre of a Negro voter registration drive led by Martin Luther King (*q.v.*). Terrorism and violence, culminating in the murder of James J. Reeb, a Boston minister, led to a massive, nonviolent protest march on the state capital (*see* MONTGOMERY).

The place was known as Moore's Bluff or Moore's Landing in 1815; it was incorporated in 1820 by a company headed by William Rufus De Vane King (vice-president of the United States in 1853), who named it Selma from a poem by Ossian.

It replaced Cahaba (capital of Alabama from 1820 to 1826) as county seat in 1865. Its chief pre-Civil War showplace is Sturdivant Hall, formerly the Gilliam home. For comparative population figures *see* table in ALABAMA: *Population.* (W. T. Jo.)

SELOUS, FREDERICK COURTENEY (1851–1917), English hunter and explorer in south-central Africa whose travels added to the knowledge of Rhodesia, was born in London on Dec. 31, 1851, and was educated at Rugby and in Germany. In 1871 he went to South Africa and in 1872 traveled to Matabeleland where he hunted big game. He then wrote *A Hunter's Wanderings in Africa* (1881).

For 18 years Selous explored and hunted over the country between the Limpopo and the Congo basin, collecting specimens of many kinds. In 1890 he entered the service of the British South Africa company and was active in the successful pioneer expedition to Mashonaland and in the arrangements whereby the district of Manica, near the Portuguese frontier, was brought under British control.

Selous summarized his travels in "Twenty Years in Zambesia," *Geogr. J.*, i (1893). His account of the Matabele War, in which he was wounded in 1893, was entitled *Sunshine and Storm in Rhodesia* (1896). Selous then settled in England but made hunting expeditions to many parts of the world. He was killed in action near Kisaki in Tanganyika on Jan. 4, 1917, during World War I.

See J. G. Millais, *Life of Frederick Courteney Selous* (1918). (R. L. Hl.)

SELWYN, GEORGE AUGUSTUS (1809–1878), Anglican bishop of New Zealand, in whose memory Selwyn College, Cambridge, was built by public subscription, was born in Hampstead on April 5, 1809, and educated at Eton and St. John's College, Cambridge. In 1841 he was appointed first bishop of New Zealand, then just declared to be under the British crown. A man of great heart and physical strength, he acquired the Maori language on the voyage from England and soon won the confidence and affection of the Maori people. The first Maori War made him unpopular with both parties, since he became suspect to the Maoris as an Englishman and was hated by many settlers as an upholder of native rights. But both sides came in the end to respect his courage and integrity and he had much influence in creating a New Zealand with room for both races. In 1867 he accepted the see of Lichfield, where he died on April 11, 1878.

SEMANG, a nomadic Negrito hill people of the Malay Peninsula (Thailand and Malaysia); trustworthy population data were unavailable in the 1960s (best estimates put their total number at less than 3,000, with only about 100 in Thailand). Wandering in small bands, and living on game and forest products, they use the blowgun (*q.v.*) with poison darts. Men wear a waistcloth and women a wraparound (skirt) of bark beaten with a mallet. Scarification is practised by wounding the skin with the edge of a sugarcane leaf and rubbing in charcoal powder. They play bamboo instruments, the Jew's harp, and the nose flute; the dead are buried with food and drink in simple graves. Leaf-covered dwellings have a framework of saplings with no side walls; sleeping mats are laid on a floor of small crossed logs. The Semang (called Ngo in Thailand) have no tribal organization. The basic group, which includes an elder male with his immediate family (and perhaps married sons and daughters), breaks up when whim or necessity dictate. They speak one of the Austroasiatic languages (*q.v.*), which (along with their surprisingly well-developed religion) suggests outside influences. *See* also NEGRITO; MALAYSIA.

SEMANTICS, GENERAL, a doctrine and educational discipline developed by Alfred Korzybski (1879–1950), a Polish scholar and engineer who lived in the U.S. from 1917. The term "semantics" was used to indicate concern with the many ways in which meanings of words and other symbols influence the responses of human beings to their environment and to each other (called "evaluation" by Korzybski and his followers). The adjective "general" was added to avoid confusion with other logical and linguistic studies called semantics (*see* SEMANTICS IN LINGUISTICS and SEMANTICS IN LOGIC).

In his chief book, *Science and Sanity* (1933; 3rd ed., 1948), Korzybski argued that prevailing habits of thought have lagged far behind the linguistic and logical assumptions of modern science. He drew upon relativity theory, quantum mechanics, colloidal chemistry, neurology and mathematical logic as evidence of a revolution against so-called "Aristotelian evaluative habits." Current thought and practice in nonscientific situations were held by him to be seriously hindered by defective habits traced back to Aristotle's logic and its influence on western culture. The alleged Aristotelian assumptions attacked include: (1) the claim that subject and predicate are identical (the use of "the 'is' of identity"); (2) the exclusion of any but the two truth-values of truth and falsity (as shown by the law of excluded middle); and (3) the law of contradiction (nothing is both *A* and not-*A*).

Modern science is held to have shown that these assumptions represent at best oversimplifications of the true structure of reality. The resulting "evaluative habits," resulting from an "Aristotelian orientation," are marked by dogmatism, rigidity and lack of emotional balance. These defects show themselves in confusion between symbols and the realities for which they ought to stand, inattention to the limitations of abstraction, willingness to make sharp "either-or" distinctions and uncontrolled, "trigger" responses to stimuli. The condition of disorientation thus produced deserves to be called "un-sanity," and calls urgently for therapy.

On the theoretical level, Korzybski elaborated a complex doctrine that he called "non-Aristotelian" (abbreviated to the symbol "Ā" by general semanticists). Much emphasis was laid, however, upon practical training in better evaluative habits. As simple but useful aids to the learning of such habits, he advised the use of "indexing" (so that one speaks of "man_1," "man_2," etc., to distinguish different senses), "dating" (*e.g.*, "Roosevelt_{1930}," "Roosevelt_{1940}") and accompanying all statements by an implicit "et cetera" (shown by the symbol ".,") to indicate awareness of factors omitted in any process of abstraction. To facilitate "awareness of abstracting," he also invented an ingenious model known as the "Structural Differential."

An Institute of General Semantics (Lakeville, Conn.) was established in 1938 to give training in Korzybski's methods. The International Society for General Semantics established a quarterly journal *ETC*. Numerous attempts have been made to apply general semantics to the teaching of English, speech correction, psychotherapy and many other fields. The enthusiasm of many devoted adherents of general semantics is not shared by most academic scholars in related disciplines.

See I. J. Lee, "General Semantics 1952," *ETC* (winter, 1952), which contains useful references, and M. Black, *Language and Philosophy*, ch. x (1949). (M. Bk.)

SEMANTICS IN LINGUISTICS. The word "semantics" as a noun is a modern word, based on the Greek adjective *semantikos* ("significant") which was used by Aristotle in a linguistic sense in *On Interpretation*. The first known use of the word as a noun appeared in a review of Arsène Darmesteter's book *La Vie des mots étudiée dans leurs significations* (Paris, 1887) by Gaston Paris in the *Journal des savants*, p. 65 (Feb. 1887), but the expression used by Paris ("this part of linguistics, so subtle and yet so new, that is called semantics") shows clearly that the word had been used before. From French the word entered quickly into other languages.

The word "semasiology," however, had already been proposed by the German Latinist Karl Reisig in his *Vorlesungen über lateinische Sprachwissenschaft*, published in Leipzig in 1839 (reprinted in Berlin, 1881–90). A kind of study of lexicological semantics was written by the Neoplatonist Proclus in the 5th century in his commentary on Plato's *Cratylus*. The philosophical dispute between the exponents of realism and idealism (*qq.v.*) has gone on through the ages. In modern times Lady Welby (*Significs*), George Boole, C. S. Peirce and their successors (Bertrand Russell, Rudolf Carnap, and others) have pursued the problem of meaning with great acumen and originality. More recent is the view that there is a close connection between probability and

meaning, intimately related to variation in language, which is a constant process, and to selection, which repairs the ravages of variation. Selective variation in language tends to maintain an equilibrium in meaning as in all other linguistic features. A word used with great frequency is low in semantic value, important as it may be functionally or grammatically; content of meaning is enhanced by relative rareness, and affectivity is higher in words upon the use of which restrictions are placed by context or even by extralinguistic factors such as taboo. Meaning withal "means" something, namely intelligibility or understanding on the part both of speaker (or writer) and hearer (or reader) and this is perhaps the simplest way of describing it, as "linguistic goal-directed activity." The analogy of modern communication theory and even of servomechanisms and computing machines has pointed to and emphasized this view of what "meaning" is, and of how it is conveyed symbolically.

In the 19th century neogrammarians (*q.v.*) saw language in two aspects, a "psychological" and a "phonetic." The phonetic was considered as purely physiological, and phonetic changes, then labeled phonetic laws, were seen to be highly regular. Therefore the word "semantic" was at first opposed to the word "phonetic" as the signifying part of language, in opposition to the nonsignifying part—in the individual speech-sound. But the work of the Prague school of linguistics, since about 1920, has shown that each sound in itself—or more exactly each class of sound, *t, d, p, b,* etc.—is not indeed significant but distinctive, *i.e.,* a pair *b : p* distinguishes two meanings. If "bit" and "pit" are two different words in English, the difference in meaning hinges obviously on the difference between *b* and *p;* this difference, called opposition, is therefore distinctive. There are languages, such as the Swiss-German dialects, in which *p* and *b* are mere nondistinctive variations of the same phoneme. Some differences (technically, oppositions) that are such in English are not so in other languages. English distinguishes a velar ŋ (as in "sing," "wing") and a dental *n* (as in "sin," "win"); Italian or Spanish, although having the sounds ŋ and *n,* for example, in Italian *unto* and *ungo,* do not attach any really linguistic significance to this difference, which is mechanically determined by the adjoining sounds *t* and *g.* A distinction between semantic and phonetic cannot then be sharply maintained. The whole of language is a unity, and a nonsignificant part is not to be separated from the remainder.

The definition of semantics is then the study of the connection between a linguistic feature and the corresponding mental process or symbolism in the act of speaking. In English the form "I love" represents action in the present, "I loved" in the past, but the meaning of "I went" with respect to "I go" is identical to that of "I loved" with respect to "I love." The same holds true for "boy," "boys"; "mouse," "mice"; "ox," "oxen"; and for "clear," "clearer"; "good," "better." English expresses the comparative or the plural or the past in different ways, for grammatical, not semantic reasons. There is no necessary invariant correspondence between form and meaning in language, which is a systematic symbolism, the meaning of which depends almost entirely upon a conventional tie between a symbol and that which it symbolizes.

Thus language tends to eliminate homonyms when homonymy becomes destructive to mutual understanding. In those regions of France where Latin *molere* "to grind," and *mulgere* "to milk," came to coincide, *mulgere* was replaced by *trahere* (*traire*), "to draw"; and where the names of the "cat" and the "dog" or the "cat" and the "rooster" came to have the same form, one of the two (or sometimes both) was replaced by another word (*e.g.,* "rooster" by "pheasant").

The connection between language and human mental processes has been conceived in several ways. One school of thought simply ignores all mental processes as unnecessary and confusing. According to this view, language must be studied by itself, without any reference to meaning. Apart from the obvious fact that it cannot be explained how, without some kind of mental process, anything about language can be asserted or understood, or that discussion of abstract terms usually produces significant responses only in other linguistic terms, it is clear that the theory simply "solves" the problem by suppressing the fact that the solution is itself, like language as a whole, a response to linguistic (and mental) stimuli.

A quite different opinion has been defended by the Norwegian scholar A. Sommerfelt, who follows the French sociological school, in particular that of Émile Durkheim. "Language," says Sommerfelt, "is in principle independent of the individuals as such. It is a system of actions which the individual must learn from other older individuals, who are members of the same society as he is." However, he also admits:

> Words have become something more [than actions]: [they become] the means by which society not only acts on the surrounding world, but also conceives this world. . . . Malinowski is therefore quite right when he criticizes the usual definition of language as a means of expressing thoughts. . . . The categories of thinking are based upon language. Logic and grammar are not at all identical; the confusion of the two has damaged, it is well known, the development of language study. However, we think by means of language. In logic and in language, such as we know them in the European civilisation, we find the relationship: subject-predicate. When Aristotle, in his *Logic,* operated with the categories of substance, number, or relation, he could do so because these categories were represented in the Greek language. Our [current popular] logic is based on the categories of the Indo-European languages.

This theory cannot be accepted as it stands. Animals certainly think, in their own way and in their own world, although they do not "speak." It is moreover the daily experience of everyone to think before he speaks, or without speaking at all, and without always putting his thoughts into words; and it is the experience of every speaker that he sometimes has difficulty in putting into words just what he wishes to say. There must be, however, a connection between language and thinking. It is also certain that language to some extent influences a person's way of thinking and his whole conception of the universe, and that language helps tremendously to evolve, develop, and mature his thinking, especially during childhood. It is obvious that a child learns what a dog is, or what a tree or a bird is, by hearing them called "dog," "tree" or "bird." If he did not (and in some cultures he does not), he would not connect a Pekingese with a Dalmatian, or a cherry tree with an oak, or a sparrow with an eagle; or at least he would arrive at such an abstraction much later and with much greater difficulty. It is alleged that modern Americans have a somewhat different concept of the wolf from the Italians. To the Italian the wolf denotes a person who eats too much, to the American a man who pursues women; the two metaphors are far apart, and no Italian who has not lived in the United States would be likely to understand any of the many jokes about the American wolves, or vice versa. And there is hardly any doubt that without language Plato's or Giambattista Vico's or Immanuel Kant's philosophy could never have been elaborated, and the whole intellectual edifice of our modern culture could not have been built up.

Thus the sequence is from percept to concept to verbalization. There is a constant interaction between these three elements and necessarily language partakes of this mutual interaction and reflects it historically, not least in meaning. The fundamental mistake of ancient, medieval and Renaissance thinkers was not to consider that language is, among other things, the expression of human thinking (which of course was right) but to apply grammatical categories as if they were the only true logical categories, complete in themselves, and universal. This can be seen quite clearly even today in our grammatical terminology, which has been preserved from antiquity; *e.g.,* when the word "substantive" obviously derives from "substance." The philosophers who created the term thereby attributed not only to contemporary illiterates—which is already to go much too far—but even to Stone Age men of 5,000 years ago the idea of substance. Nor does this category of substance apply well to modern English or to Old English or to any other language living or dead, nor can it possibly apply, for language is just not built that way. "No language has been formed by an assembly of logicians," as Voltaire once wrote. It may be admitted that iron is a substance, but not freedom or light or beauty. While substances are certainly indicated by means of substantives, substantives are also

used to indicate many ideas that by no stretch of the imagination could be called substances. Likewise, while gender in French or Italian or German obviously indicates sex, it is also applied to the moon, a star, a tree, a stone, a revolution, a country, a bridge, a nose, a mountain and thousands of objects or concepts obviously devoid of natural sex. It was partly this difficulty that prompted Leonard Bloomfield and his followers to deny all connection between language and mental categories and to study language by itself, without any reference to the workings of the mind.

Language has a creative or poetic quality in the formation of philosophical concepts and of scientific constructs. Myth also has played, and still (under the name ideology) plays a part in the development of human thinking and of language. Abstract nouns—so difficult for a "primitive" mind to conceive—are originally often the names of gods or heroes; that is, of concrete, personal creatures, having human shape—legs, arms, head, teeth. They were only much greater, much more powerful than normal men and women, and they possessed to a maximum extent some particular quality that is found among men and women in greater or lesser degree. Aphrodite would be a most beautiful woman, Ares an extremely strong man, Athena immensely wise and so on. It was in part through myth that the human mind bridged the enormous gap from words such as "dog," "wolf," "man," "stone," to words such as "beauty," "generosity," "freedom," "width," "greatness," "virtue," "love," etc. And this helps to explain why such words, contrary to what should logically be expected, are endowed with gender—that is, with sex—in all languages that have kept such a distinction. It is the modern remainder, and reminder, of their original divine nature.

Names of actions—birth, murder, conspiracy, destruction, deliverance—also usually have gender in many languages and have a similar origin as abstracts; the suffixes are frequently the same: *cf.* Eng. "birth," "mirth," "strength." Objects or phenomena which are sexless—stone, water, thunder, star, moon—were also endowed with life for primitive man, as can easily be shown not only by the adoration of these objects or phenomena in ancient religions (Persian, Roman, etc.) but also by the fact that they are endowed with sex, and precisely in significant couples: sun, moon; earth, sky; fire, water. It is interesting to observe that in those languages where the sun and fire are masculine, the moon and water are feminine; but when the moon and water are masculine, then the sun and fire are feminine (*e.g.*, Lat. *sol* m., *luna* f.; but Ger. *die Sonne* f., *der Mond* m.).

The category of the noun, which is unintelligible as long as substances and other logical or philosophical concepts are used, becomes quite clear in the magical realm of poetry, where stones dance and trees sing; nouns indicate persons or objects or phenomena or qualities considered as persons (or deities, which is linguistically the same). But it is not only primitive man who is a poet: in the act of speaking, all are poets. The scholar, coming back from his library, will personify his automobile, just as any primitive man might. In modern English this process is repeated every day. The suffix *-er* was originally used for agents, for persons who are engaged in a certain activity: "love," "lover"; "kill," "killer"; "drive," "driver"; or for means of action, and such names are continually being formed with this suffix: "starter," "steamer," "liner," "sweater," "buzzer," "fighter," "lighter," "diner," "sleeper," "propeller," "silencer," "nutcracker," "breaker," "trailer"; and the same suffix is used more and more for acts or actions: "thriller," "chiller," "shocker," "puzzler," "opener," "starter," "howler," "screamer" to denote an action or event that thrills, chills, shocks, puzzles, that opens, that starts, that simulates howls or screams. English, so to speak, treats actions and events as living things, especially in vivid, colloquial speech, and in slang. The like is true for other suffixes ("rockette," "majorette," "usherette," "kitchenette," "dinette," "stopette").

That adjectives are closely connected with substantives the ancient grammarians knew quite well, since the two words are merely two adjectives qualifying a noun: *nomen substantiuum, nomen adiectiuum*. The *nomen adiectiuum* is the noun that is added (*adiectum*) to the *nomen substantiuum* as an indication of a special quality which the noun possesses in the particular circumstance to which the speaker refers: the white cow as opposed to the black cow or the yellow cow. While the noun, when it indicates a quality, indicates the totality of it, the adjective indicates the quality in a specific and concrete situation and with reference to another noun. Or again it may itself be used as a substantive: "the good," "the true," "the beautiful."

The concept of quality requires a much greater degree of abstraction than that of object or person. It is much easier to conceive of a cow or a stone than to conceive ideas such as big or white or good. The history of philosophy, which is after all the history of human thinking, starts with the philosophies of substance (*i.e.*, objects—water, fire, air, earth) and progresses only with George Berkeley and Kant to the ideas of quality (*i.e.*, philosophically, of sensations: an object has no inner reality, it is only a bundle of sensations; it can be defined only as being white, sweet, tender, etc.). The study of Indo-European grammar confirms perfectly this evolution. Adjectives in Indo-European languages that designate qualities are used freely as nouns. The endings of the adjectives are the same as those of the nouns, and even change of gender, which is considered as peculiar to adjectives, occurs frequently also with nouns: Lat. *lupus, lupa; equus, equa*, like *bonus, bona*. Latin preserves at least two examples in which the development is quite obvious. Latin *uber* means "udder," "breast," and it is certainly an old Indo-European word (*cf.* Eng. "udder," Gr. *outhar*). But in Latin it is also normally used as an adjective (with one ending) with the meaning "productive," "fertile," "abundant"; *uber ager* is a "fertile field"—originally an "udder field"; that is, a field comparable to an udder in fertility. Likewise *uetus* meant originally "year" (Gr. *wetus*, Sanskrit *vatsás* "year"), and was used at first of wine, then plants or animals or humans; *uetus uinum* was a "one-year-old wine," whence later the adjectival meaning "old." In other words, adjectives were once nothing but nouns, and they testify to the metaphorical, *i.e.*, poetic nature of language. The process is reproduced in our modern languages especially by names of colours: a "violet sky" is not a sky made of violets, but a sky which has its colour in common with violets; likewise a "rose opal" is an opal which has a rosy hue. In French and in Italian such adjectives are not declined for gender—in other words, they have still the form of nouns: Fr. *une robe rose, un ciel violet;* It. *un vestito rosa, un nastro viola.*

The article, both definite and indefinite, is a very late acquisition of the Indo-European languages (and, for that matter, of many other languages). Indo-European languages had no article of any kind, and the conservative Baltic and Slavonic languages still have no article (with the isolated exception of Bulgarian). Homeric Greek had no real article; the definite article was therefore a development of classical Greek (the indefinite article arrived even later). Classical Latin had no article either, but spoken Latin certainly had it in the imperial period, and from there it spread to all the Romance languages, and the modern Germanic languages have it (though Gothic still lacked it). This grammatical device, though not indispensable, contributed to the growth both of abstraction ("the good") and of identification ("the stone" as distinguished from "stone" in general).

There was a similar evolution in the verb system. While the verbal system of Indo-European languages was based on aspect (indicating the manner of the action—perfective, imperfective, iterative, unique, inceptive, etc.), in modern languages, especially the western ones, the verb is based on the notion of time (Eng "tense"). It is true that the English or French verb has frequently some aspectual characteristics ("I was going"), but the fact remains that no finite verbal form ("I write," "I wrote," "I shall write") in English, French, Italian or German can be conceived outside time; it must definitely be a present, a past or a future, whereas the aspectual character, rarely predominant, may even be entirely absent. The same trend from aspect to time may be observed in Semitic languages; it is impossible to reconstruct any real tenses for proto-Semitic any more than for Indo-European. This is easy to understand, for the concept of time is weak among primitives, as it is among children: "The category of aspect is more concrete than the category of time, and

in the course of the history of the Indo-European languages, we see aspect losing importance, time gaining it" (Antoine Meillet).

However, this "linguistic" time is, like every linguistic category, an imaginative, subjective quantity. Just as gender is not sex, so linguistic time is neither physical nor mathematical time. Language freely uses the future for the present ("This will be John"), the past for the present ("If I had two dollars . . ."), the present for the past (*praesens historicum*), the present for the future (*praesens pro futuro*), etc.; and these two last uses are so frequent that the Latin grammarians speak of a present present (*praesens praesens*).

Moreover, from a mathematical point of view, past and future are two infinite, equivalent quantities; linguistically they are quite different. In fact, the past is known; the future is unknown. The consequence is that many languages have a past, or even two or three or more, but no future (*e.g.*, Gothic); the past appears long before the future, and it is much more stable and more developed. The future not only appears at a very advanced stage of civilization, but remains shaky and evolves with great difficulty into a real prospective, objective future, equivalent to the past; it remains for a very long time either a potential or a volitive or a debilitive future, for man conceives with difficulty of future events as really happening in the same way that past events have happened; he thinks of them as events he wants to happen ("I will go"), or that must happen ("I shall go") or that may happen ("Tomorrow I may go to New York"). Even in English the future is not on the same level with the past. "I wrote" is a simple, factual form; "I shall write" or "I will write" are compound forms with verbs implying ideas different from those of simply expressing the future time.

Lexicological problems are not essentially different from morphological or syntactical problems. The history of words expressing the ideas of being and becoming furnishes a good example. It is well known that the human mind conceives much earlier and more easily essence rather than change, objects than processes. It has taken thousands of years of philosophizing to prove that the world is in perpetual flux. Ancient, medieval and Renaissance philosophers, with the exception of Heraclitus, investigated what the world is, of what substance or substances it is formed. Modern philosophy is a new philosophy of becoming. Language reflects this philosophical evolution. While the idea of being had been reached early in Indo-European (roots **es-* and **bhu-*, Eng. "I am," "I be"), the idea of becoming was late and therefore expressed in a different way in every single Indo-European group of languages: Lat. *fio*, Gr. *gignomai*, Ger. *ich werde* (akin to Lat. *uertere* "to turn," *cf.* Eng. "He turned red"). Modern Spanish and modern Russian do not have one verb to express such an idea, but use different words, proving that the concept is neither clear nor unified (Spanish *ponerse, hacerse, llegar a ser*, etc.). Even English, besides the usual "to become," has "to grow," "to turn," "to get," "to wax." Verbs meaning "to become" seem to be somewhat unstable: Old English *weorþan* disappeared, and so did Lat. *fio*, being replaced by Fr. *devenir*, It. *divenire*, etc. It is very difficult to express in Spanish the Hegelian concept of *das Werden*, as opposed to *das Sein*.

The study of lexicology shows clearly that language is not entirely the product of economic, technical, social or political and other environmental conditions. It is also the product of man's imagination, like poetry, with which it is closely allied, for both spring from the same source. Almost any word can give a shining example of this obvious truth. The American calls his automobile a car, using a word that the Celts used 3,000 years ago for a heavy, two-wheeled wagon drawn by animals; no amount of changes or technical improvements have been able to change the word. On the other hand, words for child, boy, girl, bad, small, etc., have changed several times in the last centuries, and are still changing ("kid," "bambino," "lad," "fellow," "lass," "gal," "doll," "baby," "stinker," "teeny"), although no new type of girl or boy or child has been imported from abroad or transformed through technical or genetic improvements. But the need for poetic expressiveness prompts the speaker to replace such words constantly, because the old ones soon appear prosaic and colourless, through overuse. There is an inverse ratio between frequency of usage and affectivity.

Language being a poetic creation, it is at first normally concrete, for poetry is by its nature concrete, describing things that can be seen, smelled, and touched. The process of linguistic change, although infinitely varied, is almost inevitably one that goes from the concrete to the abstract, again and again and again. It was noted above that aspect, which is concrete, was replaced progressively by tense, which is more abstract; language always uses concrete tools to express abstract thoughts. In the English "I have seen" the "have" is a purely grammatical tool, without any concrete value of its own; but its ancient concrete, plastic use can still be seen in phrases such as "I have two dollars" or even better "I have the key in my hand" (now being replaced by the addition of another more concrete verb, "I've got the key," "I've got two dollars"). Likewise, abstract words of philosophy or religion may easily be traced to concrete, sensuous expressions: "absolute" is that which is "untied" from something (like a dog); "abstract" is that which is "drawn out of somewhere" (like a loaf from the oven); "concept" is that which is "taken together" (an image reproduced in "comprehend" and now in "to grasp"); idea comes from Greek *widea*, that is, from the root **wid-* "to see" (Eng. "vision," "video," "providence," etc.). To take the verb "to become," discussed above, the English word is a compound of the preverb *by, be-* and the verb "to come"; the German *werden* is a verb once meaning "to turn," preserved in Russian *vertét'* and Lat. *uertere* "to turn," whence Eng. "convert," "pervert," "extrovert" (*cf.* for the meaning Eng. "He turned red"); Spanish *ponerse* is "to put oneself"; Gr. *gignomai* contains the root *gen-*, "to generate," "to engender," denoting a biological phenomenon.

Since language is a poetic creation, it follows that every semantic change may be classified under the categories called rhetorical figures, or figures of speech, under which all the metaphors of the poets were once catalogued. To say that a man is no good, meaning that he is a rascal, is to use a litotes; to say irons for fetters, or glasses for spectacles, is to use a metonymy; to say that a woman dancer is terrific or devastating, or that a man is a lady-killer, is to use a hyperbole—since ladies generally will survive such amorous experiences. All of language is a living metaphor, which is not noticed, precisely because metaphor is so amalgamated into it that it appears natural and inevitable.

SEMANTICS IN LOGIC aims at the building of an abstract theory of the relation between signs and what they mean. *Semiotic*, the study of signs and languages, is divided into three parts. *Pragmatics* studies the way languages are used. In *semantics* we abstract from usage, and are interested only in the relations between signs of a language and their meaning. In *syntax* we further abstract, and consider signs aside from what they mean. Semantics can be further divided: We either study existing languages or aim at an abstract theory. The former study is a branch of empirical science (*see* SEMANTICS IN LINGUISTICS), while the latter (*pure semantics*) belongs to logic.

The semantic structure of an ordinary (or natural) language is hopelessly complex because of the fact that its syntactic structure is not precisely determined and that it employs many ambiguous and vague expressions. Hence pure semantics deals only with fully formalized languages. Such languages aim at a reconstruction of ordinary discourse, trying to free it from the pitfalls of natural languages. Pure semantics in turn aims at a rigorous

theory of the way in which signs in a formalized language have meanings, and at the solution of the many problems raised by the meaning-relations. It is hoped that this theory can also be formalized, and hence pure semantics aims at the establishment of (one or more) formalized semantical systems which are adequate for a comprehensive theory of the meaning-relations and of related concepts. The most important of these semantic concepts are discussed below.

For an explanation of the logical terminology and symbols used in this article *see* Logic.

PARADOXES

The next sentence is true. The previous sentence is false.

If you consider either one of the foregoing sentences, you note that it is a perfectly simple and clear sentence of the English language. And yet the two sentences together constitute a paradox; they are a version of the ancient paradox of the liar. A (declarative) sentence must be either true or false, and cannot—of course—be both. Let us suppose that the first sentence is false. That means that the second sentence is not true. But to say that "The previous sentence is false" is not true is equivalent to the assertion that the previous sentence is not false. This in itself is not a paradox; from the assumption that the first sentence is false we have derived a contradiction, which shows only that our assumption was wrong. Hence *the first sentence is not false.* That implies that it is true, which means that the second sentence is true. But if "The previous sentence is false" is true, then *the first sentence is false.* We have now derived two contradictory results using only the rules of logic.

Another type of semantic paradox is due to Kurt Grelling. Let us classify the adjectives of the English language as to whether they are self-applicable or non-self-applicable. An adjective is self-applicable if it has the property it expresses; *e.g.*, the adjective "short" is self-applicable since it is a short word, but "long" is non-self-applicable since it is not a long word. Every adjective is either self-applicable or non-self-applicable, and cannot—of course—be both. Which is the case for the adjective "non-self-applicable"? Suppose that it is self-applicable. Then it has the property which it expresses, *i.e.*, it is non-self-applicable, contrary to our supposition. Hence *it is non-self-applicable.* This means that it does not have the property it expresses, the property of non-self-applicability. But this is just another way of saying that *it is not non-self-applicable.* We have again arrived at two contradictory results.

Paradoxes are often treated as if they were harmless amusements. But this is far from a correct evaluation of them. The above paradoxes show that English allows the derivation of contradictory conclusions by means of the rules of logic; *i.e.*, that English is inconsistent. Since it can be shown that in an inconsistent system anything at all, true or false, can be proved (this is a consequence of the law of denial of the antecedent; *see* Logic), we have to conclude that ordinary English is a language not suitable for logical arguments. And it is not the case that some simple trick will remove this inconsistency.

The root of the difficulty lies in the fact that English, in common with other natural languages, allows us to formulate its own semantic theory. We can discuss such concepts as being a true sentence (of English) and prove the basic truths about these concepts. While this appears at first to be a highly desirable feature of natural languages, Alfred Tarski showed that any language having this feature is necessarily inconsistent. He has shown for a wide variety of languages that if they enable us to discuss semantic problems about themselves and to prove at least the most basic expected results, then a paradox can be formulated in the language. Indeed, if the reader will re-examine the way we arrived at the two sets of contradictions above, he will find that we have appealed only to the most elementary semantic truths.

We are forced to the conclusion that we must never attempt to formulate the semantic system of a formalized language within the same language; we must employ a second language which is used to talk about the first one. This second language must enable us to express and prove anything that can be expressed or proved in the first language, and in addition it must be able to do more, namely, allow us to formulate a semantic theory of the first language.

The lesson we learn from the semantic paradoxes is that in order to formulate a comprehensive semantic theory for a given language we must employ a second, stronger (or richer) language.

META-LANGUAGE

The second language introduced to talk about a given language is known as the *meta-language,* while the first language is called the *object language.* It is important to note that these are relational terms: It is nonsense to ask whether a given language is a meta-language; we can only say that it is being used as a meta-language of another language at the moment. The meta-language can in turn be studied, in which case it is used as an object language, and the previous object language can be the meta-language of a third language.

When a language is used to formulate a semantic theory for a given object language, we call it a *semantic meta-language.* Thus the lesson of the semantic paradoxes is that a semantic meta-language must always be stronger than its object language. This makes the task of formalized semantics very complex: If we want to formulate a semantic theory of a given language, we employ a second, stronger language. If we want to study the semantic structure of this second language as well, Tarski's result shows that we must use a third language even stronger than the second one. This new language can, in turn, only be studied in a fourth language, etc. We are led to an infinite hierarchy of stronger and stronger languages in which each (after the first) serves as a meta-language of the previous one, and in turn serves as an object language. We cannot escape the conclusion that if the aim of a comprehensive formalized theory of the semantic structure of languages is at all attainable, it can only be achieved by means of infinitely many formalized languages.

The Model Language L.—In the following discussion we will always suppose that we are discussing some given formalized language. Since the discussion will take place in English, English is our meta-language. We have already noted that this is an unsuitable language from the logical point of view, but it is used for the sake of ease of presentation. To make some of the points more concrete, we will employ a simple language **L** as an example of an object language. **L** is a simple applied singulary functional calculus of the first order (*see* Logic), which is designed for tasks like the taking of a census. It has predicates $A, B, C, \ldots$ which express properties of human beings, and individual names $a, b, c, \ldots$ which are names of human beings; *e.g.*, B, M, and R express the properties of being a bachelor, married, and red-haired, respectively, while b, r, and s are names of John Brown, Robin Robinson, and Jim Smith. The simplest sentences of **L** are exemplified by $B(r)$, expressing that Robin Robinson is a bachelor, and $R(s)$, expressing that Jim Smith has red hair. (We will assume that the latter is true and the former is false.) More complex sentences are formed by means of sentence connectives and universal quantification; *e.g.*, $R(b) \cdot \sim B(b)$ expresses that John Brown has red hair and is not a bachelor. (We will assume that as a matter of fact he is the only red-haired non-bachelor.)

While it will be helpful to illustrate various points throughout this article in terms of **L**, we must at all times keep such examples distinct from the general discussion which applies to any formalized language.

AXIOMATIC TREATMENT

Denotation, satisfaction, determination, and truth are some of the fundamental semantic concepts. We will use these to illustrate the axiomatic treatment of semantics.

Denotation is the relation between a constant of the formalized language and the object to which it refers; *e.g.*, an individual constant denotes the individual of which it is a name. In **L**, s denotes Jim Smith, while B denotes those human beings collectively who happen to be bachelors—the class of bachelors. Classes are taken in extension; *i.e.*, we do not distinguish between two classes having the same membership. Were it the case that all bachelors

hate women and all woman-haters are bachelors, then we could also say that B denotes the class of woman-haters.

Satisfaction and Determination are relations between a propositional form and an object. A given object satisfies a propositional form if putting a name of the object in place of the variable of the form turns the form into a true sentence. The form determines the object if the object is the only thing that satisfies the form. Thus, in **L**, Jim Smith satisfies $R(x)$, Robin Robinson satisfies $\sim B(y)$, and $R(x) \cdot \sim B(x)$ determines John Brown.

Truth is a property of sentences. This use of the word "true" agrees with common-sense usage, and must be distinguished from certain other recent uses of the word. We say, *e.g.*, that a certain theory is true when it is only highly probable. In semantics we want to admit the possibility that a highly probable theory may be false and an improbable one may be true. We must also distinguish truth from opinion, no matter what the grounds of belief may be; and we must not identify the concept with that of usefulness. We are using "true" in the time-honoured sense in which Aristotle uses it in the quotation: "To say of what is that it is not, or of what is not that it is, is false; while to say of what is that it is, or of what is not that it is not, is true."

The four concepts are interrelated. For example, we can define the other three in terms of satisfaction: (1) A form *determines* an object if the object satisfies the form, and if it is the only object satisfying the form. (2) Truth is a property of sentences rather than of forms, but it is easy to find a propositional form equivalent to a given sentence. We may, *e.g.*, replace the sentence S by the form $S \cdot [x=x]$. A sentence S is *true* if any object satisfies $S \cdot [x=x]$. (3) For a definition of denotation we must distinguish between various types of constants; *e.g.*, R *denotes* the class of all objects satisfying the form Rx, while r denotes the one object (person) satisfying $r=x$. (These definitions presuppose that the object language has an equality sign.)

Axioms for Truth.—First we must have axioms specifying the conditions under which individual sentences are true. We are indebted to Tarski for giving the first precise formulation. This is perhaps the most frequently misinterpreted result of formalized semantics. On the one hand the conditions have such an appearance of obviousness that we may think them trivial; but it is often the fate of great discoveries that after they have been made we forget that it took thousands of years to find them. On the other hand many philosophers have tried to assign too great a role to these conditions; they have been taken as a definition of truth, which they are not.

What are these conditions? For any given sentence it is easy to give the condition for its being true: $R(s)$ is true if and only if Jim Smith has red hair, $B(r)$ is true if Robin Robinson is a bachelor, and "all swans are white" is true if all swans are white. These conditions are of the form

(I) X is true if and only if Y,

where in place of X we have the name of a sentence, and in place of Y we have a statement (in the meta-language, of course) of what the sentence asserts. Thus, roughly speaking, a sentence is true if and only if what it asserts *is* the case. We have a complete set of conditions if in (I) we have an axiom for each sentence of the object language. Thus (I) is an axiom schema, which is normally infinite. In the exceptional cases where there are only a finite number of sentences in the object language, (I) may be replaced by a conjunction of its instances, which will serve as a definition of truth. But in the usual case, including all non-trivial languages, the list of axioms is infinite and no such conjunction can be formed. Only this case will be discussed from here on.

While (I) determines the truth or falsity of every sentence, even the simplest generalizations do not follow from it. We need

(II) For all sentences **S**, **S** is true if
and only if $\sim$**S** is not true,

as an additional axiom, for example. While for any one sentence we can prove that it is true if and only if its negation is not true, we are unable to derive the generalized result (II) from (I). We know from the schema (I) in the meta-language of **L**; *e.g.*, that $B(r)$ is true if and only if Robin Robinson is a bachelor, and that $\sim B(r)$ is true if Robin Robinson is not a bachelor, hence $B(r)$ is true if and only if $\sim B(r)$ is not true. But we can *prove* that (II) itself does not follow from (I): Let us suppose that it does follow; *i.e.*, there is a proof of (II), given (I). Since a proof contains only a finite number of steps, only a finite number of instances of (I) can be used in the proof. But then (II) must follow from a finite number of instances of (I). Such a finite list says nothing at all about most of the sentences, hence a result about all sentences cannot be a consequence. This proves that we were mistaken in supposing that (II) follows from (I).

Similarly we will have to add

(III) For all pairs of sentences **S** and **S′**,
Sv**S′** is true if and only if **S** is true
or **S′** is true.

Since all the remaining sentence connectives can be defined in terms of $\sim$ and v, we can derive corresponding results for them from (II) and (III). It is also worth noting that some famous "laws of thought" are consequences of these axioms; *e.g.*, if we define a sentence to be *false* if its negation is true—as is customary—then it is an immediate consequence of (II) that every sentence is either true or false. *See* THOUGHT, LAWS OF.

An additional axiom which we may want to introduce is: $(\mathbf{x})\mathbf{Fx}$ is true if and only if every sentence of the form **Fa** is true, where **Fx** is a propositional form, and **Fa** results from **Fx** by replacing the variable **x** of the form by the constant **a**. While this seems to have the same intuitive appeal as (II) and (III), it can only be introduced in exceptional cases. If in **L** every human being has a name, then the axiom is correct. But let us suppose that the individual names of **L** were taken from telephone books, and that P expresses the property of being listed in at least one phone book; then every sentence of the form P**a** is true, but $(x)Px$ is false! In this case, which represents the usual situation, the proposed axiom must be rejected.

These axioms are only the bare beginning of an axiomatic treatment of truth; *e.g.*, in general it will not follow that all theorems of the object language are true; we will need one or more additional axioms to assure this. These axioms can be further strengthened by combining them with axioms of *satisfaction*. From such a set of axioms it is possible to derive the equivalences that make up Tarski's definition (*see* the next section). But a complete treatment is not to be expected, since it can be shown that no matter what list of axioms is laid down, there will be true statements about truth which do not follow from the axioms.

DEFINITION OF SEMANTIC CONCEPTS

Tarski showed that the above semantic concepts can also be introduced by definition in the meta-language. It is convenient to start with a very broad notion of satisfaction. We consider not only forms with one free variable, but we allow any number of free variables. "x is white" is a propositional form with one free variable, "x is between y and z" has three free variables, while a sentence like "all swans are white" may be considered an extreme case of a form with no free variables. Since we allow several free variables, the relation holds not between a single object and a form, but between a list of objects and the form. Since forms are built up by step-by-step procedures, our definition also proceeds in this way.

Let us give the definition for **L**. Given a form **F**, we must define what we mean by having its various parts satisfied by a given list of people. We associate one member of the list with each variable (free or bound) of **F**. The simplest parts of any form are of the type **P**(**a**) or **P**(**x**). **P**(**a**) is satisfied by any list if the person whose name **a** is has the property expressed by **P**, while **P**(**x**) is satisfied by the list if the person associated with the variable **x** has this property. We may require that all more complex forms be formed by means of negation, disjunction, and universal quantification. The negation of a form is satisfied by the list if and only if the form itself is not satisfied. The disjunction of two forms is satisfied if and only if the list satisfies at least one of the

original forms. $(\mathbf{x})\mathbf{G}\mathbf{x}$ is satisfied by the list if and only if every list differing from the given one only in the person associated with $\mathbf{x}$ satisfies $\mathbf{G}\mathbf{x}$. (In this case it makes no difference which person was associated with $\mathbf{x}$ in the given list!) Thus we define step-by-step the satisfaction relation for all parts of **F**, and hence for **F** itself. We can do the same for every propositional form in **L**.

Given the definition of satisfaction, we can define the other concepts in terms of it, as indicated above; *e.g.*, we note that it makes no difference which person was assigned to a bound variable of **F**. Hence if the form happens to be a sentence—which has no free variables—then it is either satisfied by all lists or by none. In the former case it is true, in the latter false. From this definition we can derive all instances of (I), and also such generalizations as (II) and (III). We also see from this that our definition agrees with the intuitive meaning of "true," since only in this case can it yield all the instances of (I).

In most cases these definitions are the best basis for a theory of the concepts discussed so far.

ANALYTIC TRUTH

There is a second group of semantic concepts, related to each other, which are more difficult to define than the previous ones. No entirely satisfactory treatment of these is available, and there is still considerable controversy concerning them. Rudolf Carnap gave us the first systematic approach to semantics as a whole; *i.e.*, to both concepts. Many of his ideas are used in this article.

The central concept in this group is that of analyticity. A sentence is analytically true (false) if it is true (false) purely on the basis of the meaning of its words. Opposed to these are synthetic sentences, whose truth (falsity) depends on information about the physical world. "All white swans are white" and "all bachelors are unmarried" are examples of analytic truths, while "the earth is a planet of the sun" and "Jim Smith has red hair" are synthetic truths. The negations of these sentences are examples of analytically and synthetically false sentences, respectively.

In order to define these concepts we must consider not only the intended interpretation of the symbols, but all logically possible interpretations; *e.g.*, we intend to interpret R as denoting the class of red-haired people and r to denote Robin Robinson; but it is logically possible to let R denote the class of bachelors and r to denote John Brown, as long as no axiom of **L** is violated. It will turn out that some of the constants in the object language have only one possible interpretation (these are *logical constants*), but that the constants used to express facts (*extra-logical constants*) by their very nature have many interpretations. While we have a right to decide that R should express the property of red-hairedness, it takes factual information to determine which class it denotes. As far as logic is concerned, there is no reason why the people who happen to have red hair should be the redheads of the world, it could just as easily have happened that the people who happen to be bachelors fulfill this role. This possibility (and hence the corresponding interpretation) can be eliminated only by an axiom about the membership of these classes; *e.g.*, that John Brown belongs to the class of redheads, but not to the class of bachelors. But this is a factual assertion, and is therefore not suitable as a logical axiom.

In **L** an interpretation tells us (1) which class of human beings each predicate denotes; (2) which human being is denoted by each name; (3) which operation on a propositional form is denoted by negation; (4) by universal quantification; and (5) which operation on a pair of forms is denoted by disjunction. Given this information, we can define satisfaction—as we did above—relative to these meanings of the constants. A form satisfied by all lists is said to be *valid* under this interpretation. If all axioms are valid under the interpretation, if the rules allow us to infer only valid conclusions from valid premisses, and unless the interpretation is trivial in the sense that it makes all sentences valid, we then call the interpretation a *sound* interpretation, or a *model* of **L**. It is possible to show that negation, disjunction, and universal quantification have the same denotation in all models, while the predicates and individual names all have a wide range of possible interpretations.

A sentence that is valid in all models is *analytically true*; a sentence valid in no model is *analytically false* (or *self-contradictory*). An *analytic* sentence is one that is analytically true or analytically false. By the Law of the Excluded Middle, a sentence is either analytically true or not analytically true, but the latter by no means assures us that it is analytically false. In this "middle" lies the vast group of *synthetic* (or *factual*) sentences, which are valid in some but not all models. $R(r) \vee \sim R(r)$ is analytically true; no matter what class R denotes and no matter who r is, he either does or does not belong to this class. But $R(r)$ is factual; it is valid if R denotes the class of redheads and r denotes Jim Smith, and it is not valid if R denotes the class of bachelors and r denotes Robin Robinson.

It is a consequence of the above definitions that all theorems of **L** are analytically true, and that all analytically true sentences are theorems. But the latter does not hold for all formalized languages, due to the impossibility of giving a complete formalization of advanced branches of logic. (*See* LOGIC.) This is the source of many difficulties in the general definition of analyticity. Because of the incompleteness of our axioms certain logical constants admit more than one interpretation, and the definition of analyticity cannot be as simple as for **L**. There is every reason to hope, however, that semantics will overcome these difficulties.

Many concepts can be defined in terms of those just discussed. A few of these are: **S** and **S′** are *logically equivalent* if $\mathbf{S} \equiv \mathbf{S}'$ is analytically true. **S′** is a *logical consequence* of **S** if $\mathbf{S} \supset \mathbf{S}'$ is analytically true. **S** and **S′** are *consistent* if $\mathbf{S} \cdot \mathbf{S}'$ is not analytically false. Two constants are *synonymous* if they are given the same interpretation by every model. A formalized language is *complete* if every analytically true sentence is a theorem. (This last definition must be modified somewhat in languages having restrictions on quantification.)

Criticism of These Concepts.—The above concepts have been severely criticized from various points of view. W. V. Quine has even presented a strong argument to show that no sharp distinction can be made between analytic and synthetic sentences. The arguments of Quine, and of a number of other philosophers, are based on examples from natural languages in which we are unable to say whether a given sentence is analytic or synthetic. It is admitted by these critics that a certain class of sentences, the so-called *logical truths*, are clearly analytically true. Thus there is no objection to sentences like $B(r) \supset B(r)$. But what of a sentence like $B(r) \supset \sim M(r)$? How do we know that this is true purely on the basis of the meaning of the constants? We could interpret B to be the class of redheads, give M its usual meaning, and let r denote John Brown; then the sentence is false.

"All swans are white" is a good test case for these objections. The word "swan" was for a long time applied only to certain heavy-bodied, long-necked, aquatic birds with white plumage. Then a new species was discovered in Australia that was just like these, only the birds were black. The English language could have developed along either of two lines: We could use "swan" in a broader sense from then on, and speak of black swans (which is what has happened), or we could give a new name to the Australian species, say "gwan," and describe gwans as just like swans except in their colour. It certainly takes factual information to know which line was followed, but this type of factual information is no more relevant to the question of analyticity than information about how the axioms were chosen. What is relevant is that if the former line is followed, then "all swans are white" is factual and false; while under the latter procedure whiteness is part of the meaning of "swan," hence the sentence is analytically true. This sentence is analytic if and only if it is true, hence we cannot accept its classification as true or false without accepting its classification as analytic or synthetic.

The lesson to be learned from this example is that we must have complete information about the meaning of all the words in the object language, hence we must have axioms not only for the logical constants, but also for extra-logical constants; *e.g.*, we will have $B(x) \supset_x \sim M(x)$ as an axiom of **L**. Then $B(r) \supset \sim M(r)$ is analytically true, because any interpretation under which it is not valid fails to make one of the axioms valid, and hence

is not a model. Axioms which restrict the usage of extra-logical constants are called *meaning postulates*. It can be shown that the examples constructed to demonstrate that the concept of analyticity is unsound show rather that there is some question about the meaning postulates; *i.e.*, of the way certain words are used. This is not at all surprising since the examples are always chosen from a natural language. These difficulties are resolved by the fact that a language is not considered fully formalized unless all the axioms, including the meaning postulates, are explicitly stated.

TWO KINDS OF MEANING

We are indebted to J. S. Mill and even more to Gottlob Frege for showing clearly that names have two kinds of meaning. On the one hand we could take the meaning of R to be the object to which it refers, the class of red-haired people; on the other hand we could take as the meaning the idea which it calls to our minds, namely the concept of red-hairedness. The former is the *denotation* of R, the latter is its *sense* (or *connotation*). (*See* MEANING; CONNOTATION; DENOTATION.) Let R' denote the class of all those red-haired people who have no more than 1,000,000,000 hairs. Since it so happens that no one has more than 1,000,000,000 hairs, R and R' have the same denotation. But since their definitions are not logically equivalent, they have different senses. The denotation of R is a class of human beings; and its sense is a concept of this class. The sense of a term determines its denotation, but the same object may have many different concepts.

This distinction is closely related to the distinction between analytic and synthetic truth. If in an analytically true sentence we replace a term by another having the same sense, the result is also analytically true. If we substitute a term with the same denotation but a different sense, the result must again be true, but it need not be analytically true. This is due to the fact that while the sense uniquely determines the denotation, it takes factual knowledge to find out what this denotation is. Hence in order to establish the truth of the resulting sentence we may need factual information concerning the identity of the two denotations. "Woman" and "adult female human being" have the same sense, while "woman under ten feet tall" has the same denotation but a different sense. "All women are women" is analytically true, and so is "all women are adult female human beings"; but while "all women are women under ten feet tall" is true, we must have factual information to establish its truth.

Individual names also have two kinds of meaning, which is more easily seen for descriptions than for proper names. "The 32nd president of the U.S.A." and "the first person to be elected president of the U.S.A. four times" both denote Franklin Delano Roosevelt, but they have different senses as can be seen from the fact that we must know some American history to know that they have the same denotation. The distinction can even be extended to sentences: A sentence is said to denote its truth-value (*i.e.*, truth or falsity), and to have as its sense the proposition which it expresses. (In this usage propositions are both abstract and objective.)

Any theory of meaning must overcome certain difficulties raised by descriptions. "The so-and-so" has a clear-cut denotation only if there is one and only one so-and-so. What is the denotation, *e.g.*, of "the king of England in 1953"? And how are sentences containing such descriptions to be classified as true or false? A second type of difficulty is raised by sentences like "I know that Franklin Delano Roosevelt was the 32nd president of the U.S.A." This sentence differs from "I know that Franklin Delano Roosevelt was Franklin Delano Roosevelt" only in the interchanging of two terms having the same denotation, hence the former must be true, since the latter is. But if I am sufficiently ignorant the former sentence is false.

Bertrand Russell suggested a way of overcoming these difficulties by a new analysis of descriptions. He asserted that a sentence containing a description is a condensation of a more complex sentence; *e.g.*, "Franklin Delano Roosevelt was the 32nd president of the U.S.A." is an abbreviation of "there was one and only one person who was the 32nd president of the U.S.A., and Franklin Delano Roosevelt was this person." Under this analysis all sentences of the form "the so-and-so is . . ." are false if there is no so-and-so or if there is more than one. Thus the sentences "the king of England in 1953 was tall" and "the king of England in 1953 was not tall" are not contradictories, but are both false. According to Russell, descriptions do not function as names, and there is no need to assign a denotation to them. And if we rewrite the first "I know . . ." sentence according to Russell's analysis, we see that it has an entirely different structure from the second one.

Though this approach overcomes the difficulties without using the Frege distinction, it raises certain problems of its own which have induced other investigators to return to Frege's approach. The difficulty of the denotation of "the king of England in 1953" is overcome by Frege by assigning denotations to such descriptions by some arbitrary convention. The two major systems that employ this procedure differ as to the way in which they treat the second difficulty. Carnap maintains a distinction between the *extension* and *intension* of terms which is very similar to the distinction between denotation and sense. But Carnap's rule of substitution (of a term for another having the same extension) is restricted so that it cannot be applied in contexts like "I know. . . ." Alonzo Church worked out a suggestion of Frege's according to which names in contexts like "I know . . ." are not used in the customary manner, but *obliquely*. This means that they are used not as names of their denotation, as usual, but as names of their sense. Thus the sentence above is not about the person F. D. Roosevelt, but about two different concepts of this person.

While this analysis seems like the most natural one, it obligates us to build a formalized language in which a name is not used with different denotations at different times. This means that we need a name for the sense of each name. And then, of course, we need a name for the sense of the new name, etc. This leads to a very complex hierarchy of names and concepts. Such an *intensional* system was formulated by Church, and to anyone who accepts the Frege analysis this system represents as much progress over the usual (extensional) formalized languages, as those represent over unformalized languages. But, because of the very great complexity of the Church system, it remains to be seen whether it can stand the test of detailed scrutiny.

Abstract Entities.—The problem of treating abstract entities, like the sense of a name, is the most controversial topic in semantics. Many logicians have strong philosophical objections to the treatment of concepts as in any sense on a par with physical objects. Quine in particular has devoted considerable effort to a reconstruction of logic along nominalist lines (*see* NOMINALISM), trying to rid the foundations of what are usually called Platonic doctrines. So far the nominalist systems have only been able to cope with a small part of logic. On the other hand, the type of Platonist system advocated by Church or Carnap runs the serious risk of being inconsistent. It remains to be seen whether nominalist or Platonist systems prove more successful in the formalization of semantics.

SEMAPHORE, a method of signaling by means of flags, lights or arms. Before the invention of the telegraph, semaphore signaling from high towers was used to transmit messages between

distant points. Movable arms, or rows of lights simulating arms, displayed from towers and used to signal railroad trains are modern semaphores. Semaphore signaling between ships is accomplished by men who hold a small flag in each hand and, with arms extended, move them to different angles to indicate letters of the alphabet. While such signaling has been largely superseded by radio it will probably continue in use at times when radio silence is necessary.

See SIGNAL COMMUNICATION, MILITARY. (M. R. D.)

SEMARANG, capital of Central Java province and Semarang residency and one of the chief towns and ports of Java, Indon., is a centre of commerce situated almost centrally on the north coast, 250 mi. (402 km.) E of Jakarta. Pop. (1961) 503,153.

The town, a short distance inland from the port, lies on the banks of the Kali Semarang, above where the Kali Baru branches from it. Like Jakarta, it is divided into two parts: the old native town near the coast, thickly housed, with narrow streets but with some good shops, hotels, business houses, and churches (in former times it was surrounded by a moat, with forts); and a newer town, farther inland, where there are various government and public buildings, including a military hospital, and also hotels, restaurants, and in the town square a mosque; the square also has recreation grounds. The two districts are connected by the fine Bojong road. South of this road is a picturesque residential hill suburb (Tjandi), 500 ft. (150 m.) above the sea. The town is linked by rail with Surakarta, Jogjakarta, Madiun, and Surabaja, and by steam streetcar with Tjirebon, where connection is made with the railway to Bandung and Jakarta. Of interest in the vicinity of Semarang are the towns of Demak and Salatiga.

Although Semarang is the third port in Java, its harbour, at the mouth of the Kali Baru, is unprotected against the northwest monsoon, which can cause suspension of port operations. Vessels anchor about 3 mi. (5 km.) out, and for the protection of the lighters which take their cargo, there is a harbour, the western pierhead of which extends 5,249 ft. (1,600 m.) into the sea, to prevent the mouth from silting up. This harbour has two customhouse basins, and there is a fishing vessel harbour. The port is connected by rail and road with the hinterland, and by cable with Jakarta, Surabaja, and Balikpapan in Kalimantan (Indonesian Borneo). The river between the town and the sea is canalized for traffic. Industries include the manufacture of machinery and textiles. Wooden lighters, motor boats, and tugs are built at a yard southwest of the port. Fishing is also an important industry. Rubber, coffee, sugar, and other agricultural products are exported. During World War II Semarang was occupied by the Japanese from 1942 to 1945.

SEMELE, in Greek mythology, daughter of Cadmus and Harmonia, and mother of Dionysus by Zeus. *See* DIONYSUS.

SEMENOV, NIKOLAI NIKOLAEVICH (1896–), Russian physical chemist, who was awarded the 1956 Nobel Prize in Chemistry, jointly with Sir Cyril Hinshelwood, for work on the kinetics of chemical reactions, was born at Saratov on April 15, 1896. He graduated from Petrograd University in 1917 and worked in the Leningrad Physical Technical Institute (1920–31) where he became professor in 1928. In the following year he became corresponding member, and in 1931 full member, of the Academy of Sciences of the U.S.S.R. Semenov later became director of the Institute of Chemical Physics in Moscow.

Semenov had long been known to chemists for his outstanding work on the mechanism of chemical transformations. In his book *Chemical Kinetics and Chain Reactions* (published in England in 1935) he gives an exhaustive analysis of the applications of the chain-theory to varied reactions, and especially to those involved in combination processes. He also put forward the idea of degenerate branching, in terms of which some of the mysterious phenomena associated with the induction periods of oxidation processes can be understood. Less well known is his work on the propagation of explosive waves, which appeared only in Russian. Semenov was the first Soviet citizen to win a Nobel Prize.

SEMINOLE, an American Indian tribe of Muskogean linguistic stock (*see* MUSKOGEAN INDIANS) formed in the 18th century by settlers from the Creek (*q.v.*) confederacy, primarily speakers of the Creek and Hitchiti languages. Many runaway Negro slaves joined them. In Creek the name means "wild," "nondomesticated." Early in the 1800s the Seminoles occupied former Apalachee and Timucua territory in north Florida. The Seminole wars (1817–18; 1835–42; 1855–58), caused by Seminole resistance to giving up their lands and Negro associates, resulted in the removal of most of the tribe to Indian Territory (later Oklahoma) where they became one of the Five Civilized Tribes (*q.v.*). The Second Seminole War was one of the most costly Indian wars ever fought by the U.S. Army. In the 1960s there were about 3,000 Seminoles in Oklahoma and 1,000 in southern Florida. *See* also FLORIDA: *History;* OKLAHOMA: *History;* OSCEOLA.

See J. R. Giddings, *The Exiles of Florida* (1964). (W. C. ST.)

SEMIPALATINSK, an *oblast* of the Kazakh Soviet Socialist Republic, U.S.S.R., was formed in 1939. Area 67,343 sq.mi (179,599 sq.km.). It lies just west of the Altai Mountain system and is drained by the Irtysh River in the north and by the Ayaguz in the south. These two basins are separated by the Tarbagatay and Chingiz-Tau ranges which cross the *oblast* from east to west. The climate is continental with a January average of −16° C (3.2° F) in the north and −12° (10.6°) in the south. The July average varies from 20° (68°) to 23° (74°). Parts of the large lakes of Sasykkol', Alakol', and Zaysan (fresh water) are within the boundaries of the *oblast*. Part of Zaysan Lake forms the Ust'-Kamenogorsk water reservoir.

The population, 520,299 in 1959, consists mainly of Kazakhs and Russians, but there are also Ukrainians, Tatars, and others. The *oblast* is divided into 13 *rayons*, 2 towns, and 9 settlements of town type. The two towns are Semipalatinsk (*q.v.*), the *oblast* centre, and Ayaguz, 165 mi. (266 km.) S of Semipalatinsk.

The economy is mainly agricultural, with a large number of collective and state farms. Of the total sown area in the early 1960s more than three-quarters was under grain and nearly one-fifth under fodder with small areas under technical crops (mainly sunflower) and vegetables. Livestock consists mainly of horned cattle and sheep with a smaller number of pigs, goats, and horses. There are valuable deposits of lime, graphite, gold, silver, copper, and manganese. The *oblast* is traversed by 350 mi. (563 km.) of the Turksib (Turkistan-Siberian) railway. A main road from Ayaguz runs southeast to the Chinese border. The Irtysh River is navigable. There are a number of special training and higher educational establishments in the *oblast*. *See* also KAZAKH SOVIET SOCIALIST REPUBLIC. (G. E. WR.)

SEMIPALATINSK, a town and centre of Semipalatinskaya (Semipalatinsk) Oblast' in the Kazakh Soviet Socialist Republic, U.S.S.R., lies on the Irtysh River, 560 mi. (900 km.) NNE of Alma-Ata and 445 mi. (716 km.) SE of Omsk. Pop. (1959) 156,110. The town was founded in 1718 on a site 11 mi. (18 km.) from the present one, to which it was transferred in 1778. The industry is mainly concerned with food processing and production and with building materials. The town has one of the largest meat-packing plants in the U.S.S.R., and there are leather, textile, lumber, and wool-processing works. There are a Russian-Kazakh theatre and two museums. Semipalatinsk is a junction on the Turksib railway to Arys', and a branch line links the town with the South Siberian system at Kulunda and with the Trans-Siberian at Tatarsk. (G. E. WR.)

SEMI-PELAGIANISM is a term introduced into theological discussions of the 17th century, designating the doctrine of an anti-Augustinian movement that flourished from about 429 to about 529 in southern France. As the name suggests, the spokesmen of the movement did not subscribe to pure Pelagianism but defended a position congenial to Pelagian principles (*see* PELAGIUS). Unlike Pelagians, the Semi-Pelagians believed in the universality of original sin as a corruptive force in man. They also believed that without God's grace this corruptive force could not be overcome, hence They admitted the necessity of grace for Christian life and action. But also insisted on the necessity of baptism even for infants. But against Augustine they taught that the innate corruption of man was not so great that the initiative toward Christian commitment was beyond the powers of man's native will.

This commitment was called by John Cassian *initium fidei* and

by Faustus of Riez *credulitatis affectus*. In this view man by his unaided will could desire to accept the gospel of salvation, but he could not be actually converted without help from on high. At least in later Semi-Pelagianism, divine help was conceived not as an internal empowering graciously infused by God into man but as purely external preaching or the biblical communication of the gospel, of the divine promises, and of the divine threats. The strong point for all Semi-Pelagians was the justice of God: God would not be just if man were not natively empowered to make at least the first step toward salvation; if salvation depended initially and unilaterally on God's free election of the saved, those not chosen could rightly complain that they were doomed by the mere fact of being born. The fathers of Semi-Pelagianism were monks who stressed the need of ascetical action. For them, the doctrine of Augustine made for quietism and passivity; it fostered sloth.

The Semi-Pelagian Writers.—The surviving evidences of the original movement are scanty. Yet it is clear enough that Semi-Pelagian doctrine was widespread in southern Gaul in the 5th century. The champions of the system were holy men and highly respected leaders in the church. No more than five or six can be named, and of these only three were positive influences in the history of this thought. The first was John Cassian (*see* CASSIANUS, JOHANNES), a monk formed in the East, who founded two monasteries in Marseilles. It was in his *Collations of the Fathers* (especially *Collation* XIII) that he formally proposed the earlier Semi-Pelagian theory. Because of Cassian the term *initium fidei* (initiative toward Christian commitment) became a Semi-Pelagian label. (The term was used in much the same sense before in Augustinian circles in Africa and is probably taken from the Vulgate Version of Ecclus. 25: 16 [11], or possibly from S. of Sol. 4:8 in some non-Vulgate translation of the Septuagint.)

The second Semi-Pelagian writer was Vincent, a monk of the celebrated Abbey of Lérins (*see* VINCENT, SAINT, of Lérins), who wrote, in opposition to the grace doctrine of Augustine, a work now lost, though its substantial content can be seen in the answer of Prosper of Aquitaine, *ad Obiectiones Vincentianas*. Vincent's important work, *Commonitorium*, probably was an indirect attack on Augustine, making him out to be an innovator. Vincent does not seem to have influenced Semi-Pelagianism beyond writing in its favour.

The third Semi-Pelagian theologian of importance was Faustus, bishop of Riez (*see* FAUSTUS, SAINT, of Riez), a former monk and abbot at Lérins. At the request of the Provence bishops he wrote *De gratia*, in which Semi-Pelagianism was given its final form, more naturalistic than in Cassian. Notwithstanding Faustus' insistence that he is not a Pelagian, and the fact that he uses orthodox language, his doctrine is close to Pelagianism. For Faustus, God cannot interfere with man's freedom before or after Christian conversion, and freedom itself is an inclination to virtue and faith. In this sense all faith is rooted in grace because human freedom is a grace.

The result of Semi-Pelagianism was the denial of the necessity of God's unmerited, supernatural, gracious empowering of man's will for saving action. It contradicted St. Paul and St. Augustine, the latter by papal declaration the approved Catholic doctor in the question of grace and so beyond attack.

Opposition and Condemnation.—In its early stages Semi-Pelagianism was opposed in Gaul by two polemicists, Prosper (*q.v.*) of Aquitaine and an otherwise unknown Hilary. Augustine wrote two treatises for his defenders in Gaul: *On the Predestination of the Saints* and *On the Gift of Perseverance*. But opposition did not in any way convert the Semi-Pelagians. The champions of Augustine, as Goth declared, were the victims of attack and persecution. What happened to Hilary is not known, but Prosper soon left Gaul to work at the Papal Curia; the result was that no one of stature led the Augustinian forces, which were numerically weak and of no prestige. At the time of Faustus, the symbol for Augustinianism was a certain priest, Lucidus, known only through the writings of Faustus; the latter wrote his book on grace against this obscure man, who could be safely attacked while Augustine could not. After Faustus' death, Semi-Pelagianism was still in high respect as may be seen in the biographical sketches of Gennadius, in which all Semi-Pelagians are praised and Augustine along with Prosper is disparaged.

Nevertheless the 6th century saw the decline of Semi-Pelagianism, mainly through the action of Caesarius of Arles (*see* CAESARIUS, SAINT, of Arles). Though Caesarius had been a monk at Lérins, his theology was not at all in line with the Lérins tradition, and at the instigation of Pope Felix IV (III) (526–530) he condemned Semi-Pelagianism at the so-called second Council of Orange (529). Caesarius presented the papal propositions with some of his own to a few bishops, priests, and important laymen gathered at the consecration of a church in Orange. They signed the document and it was sent to Rome for approval. In the Orange decrees the very words of Cassian and Faustus are used in the condemnation of their doctrines, but their names are not given. When the missive arrived at Rome, Pope Felix's successor, Boniface II, a friend of Caesarius, solemnly approved the conciliar decrees.

From that point on, Semi-Pelagianism was recognized as a heresy in the church. In Gaul, however, it was not entirely dead. Either before or shortly after the second Council of Orange, there was held at Valence another council which, according to the biographer of Caesarius, included bishops unfriendly to Caesarius and to his theology. The acts of this synod have not survived and it is not possible to say how far it favoured Semi-Pelagianism. In any case, the position of Caesarius with its papal confirmation was impregnable, and by the middle of the 6th century Semi-Pelagianism was no more. Future resurrections of it were renewals of Semi-Pelagian tendencies rather than the reproduction of Semi-Pelagian doctrine.

(G. WL.)

SEMIRAMIS, the Greek name of an Assyrian queen who was not only a great figure in her own age but later became the heroine of legendary exploits and left reputed monuments of herself in distant lands. The original Semiramis was undoubtedly Sammu-ramat, mother of the Assyrian king Adad-nirari III (reigned 810–782 B.C.). Her memorial stele has been found at Ashur, while an inscription at Kalakh (Nimrud) shows her to have been dominant there after the death of her husband, Shamshi-Adad V (824–810 B.C.). She seems to have been in fact the actual ruler of Assyria during the early years of her son's reign. It is also clear that she was devoted to the Babylonian god Nabu (Nebo), whose worship she substituted at Kalakh for that of its former patron-god. No more than this is known concerning the authentic Sammu-ramat.

The name and reputed acts of Semiramis are first found in Herodotus (i, 184), who ascribed to her certain earthworks, but no more, although he said that a gate of Babylon was named after her. Much more important in Herodotus are the great structures of flood protection and defense at Babylon which he ascribes to another queen, "Nitocris," who lived "five generations" after Semiramis. This name is quite unknown to Babylonian history.

On the other hand, the historian Diodorus Siculus relates the alleged exploits of a supposed Assyrian queen Semiramis, while making no mention of Nitocris. According to this story Semiramis was born of a goddess, and after being married to an Assyrian officer she captivated the king Ninus by her beauty and valour and became his wife. Soon afterward Ninus (himself a mythical king) died, leaving a son, Ninyas, by Semiramis, who herself assumed the power and reigned for many years. In that time she built Babylon and turned to the conquest of distant lands. At length, finding that Ninyas was plotting against her, she abdicated and disappeared.

The figure of Semiramis comprises, therefore, a kernel of attested fact with a later accretion of fabulous history. Some of its features indicate an Ishtar-divinity, with her mythical birth, her warlike and amorous qualities, but it has been observed that Semiramis, Ninus, and Nitocris have absorbed into themselves some of the history and the qualities of certain real characters in late Assyrian history, namely the king Sennacherib (*q.v.*), his wife Naqi'a, mother of his successor, Esarhaddon (*q.v.*), and an-

other remarkable woman of that age, Adda-guppi', the mother of "Labynetus" (Nabonidus; *q.v.*).

G.)

SEMITIC LANGUAGES. The "Semitic" languages, so named in 1781 by the German historian A. L. Schlözer because most of the people who spoke them were descended from Shem or Sem (Gen. x–xi), were spoken in Arabia, Mesopotamia, Syria and Palestine, from which they spread, beginning with the 1st millennium B.C., into Ethiopia and later into Egypt and northern Africa. The Semitic languages go back to a "proto-Semitic" language, the general structure of which can be derived from the historically attested features of the various Semitic languages. In all probability, proto-Semitic was at no time a unified language, but had dialectal variants. No single Semitic language can be said to be the representative of the proto-Semitic type. In phonology one language may come the closest to the proto-Semitic type (as is probably the case of epigraphic South Arabic) whereas for certain morphological features other languages may be considered representatives of it.

Since the Semitic languages go back to a common origin the question of the location of the speakers of this proto-Semitic language is of importance. Various regions have been so considered: Kurdistan, Mesopotamia, northern Syria (the country of ancient Amurru), Arabia and Africa. No definite answer, however, can be given to this question. The likeliest regions are those of Arabia and Mesopotamia.

Hamito-Semitic.—Semitic is a part of a larger language group, namely Hamito-Semitic. The language families that belong to Hamito-Semitic are: Semitic, Ancient Egyptian, Berber (spoken in North Africa) and Cushitic (that is, the non-Semitic languages spoken in Ethiopia). The genetic relationship among the various members of Hamito-Semitic is evident in the phonology, morphology and vocabulary. Whereas the relation between the various Semitic languages can be compared with that of, say, the various Germanic or Romance or Slavic languages, Hamito-Semitic would have more or less the role of Indo-European. (*See* AFRICAN LANGUAGES.)

Classification.—The Semitic languages are classified as North Semitic and South Semitic. North Semitic, in turn, is divided into Northeast Semitic with Akkadian as its only representative, and Northwest Semitic which includes Canaanite (Hebrew, Moabite, Phoenician), Ugaritic, Amorite and Aramaic. South Semitic is divided into Southeast Semitic, including South Arabic and Ethiopic, and into Southwest Semitic with Arabic as its representative. Of these languages, Arabic, Modern South Arabic, Hebrew, Ethiopic and Aramaic, to a limited extent, are still spoken. It is interesting to note that nearly all the Semitic languages continued to be employed as literary languages long after they had ceased to be spoken. The general features of Semitic will be discussed after the survey of the various languages.

Akkadian or Assyro-Babylonian.—This is the oldest attested Semitic language. The name Akkadian comes from Akkad, the ancient capital of Mesopotamia. The documents in the language range from 2500 B.C. to the beginning of the Christian era. There are various periods in its development. Old Akkadian is the language of the documents from *c.* 2500 to 1950 B.C. During that period the Akkadians lived side by side with the Sumerians. Toward the end of the Old Akkadian period the language divided into Babylonian and Assyrian dialects. Within the Babylonian dialect one can distinguish the following periods: Old Babylonian (*c.* 1950–1530), Middle Babylonian (*c.* 1530–1000), Neo-Babylonian (*c.* 1000–625) and Late Babylonian (after 625). In the last period Aramaic was the spoken language and Late Babylonian was the literary language. The various linguistic stages of Assyrian are: Old Assyrian (*c.* 1950–1750); Middle Assyrian (*c.* 1500–1000), strongly influenced by Babylonian; Neo-Assyrian (*c.* 1000–600). Inscriptions represent an important documentation of the literature, history, religion, magic, law, science and commerce of Mesopotamia. Because of the cultural prestige of Babylonia, Akkadian was also used in the neighbouring countries, such as Cappadocia, Elam, Canaan (Tell el Amarna letters), the Hittite empire (Bogazkoy) and Mitanni (Nuzi). Akkadian was also for a time the international language of the near east. (*See* AKKADIAN LANGUAGE.)

Canaanite.—This name came from the word Canaan, the ancient name for Palestine, Phoenicia and part of Syria. The languages that are considered Canaanite and known through direct sources are: Hebrew, Moabite and Phoenician. The older stage of Canaanite is known indirectly through the Tell el Amarna letters. (For a description of Hebrew, *see* HEBREW LANGUAGE.)

Moabite.—There is a single inscription in Moabite dating from the 8th century B.C. It is a report of Mesha, king of Moab (to the southeast of the Dead sea), on his relations with the king of Israel.

Phoenician.—This language was current in ancient times in the Phoenician cities of Tyre, Sidon, Byblos and neighbouring towns. Comparatively few inscriptions have been found in Phoenicia itself. The earliest known decipherable inscriptions are those of the kings of Byblos from the 10th century B.C. The bulk of material from Phoenicia proper consists largely of royal stelae dating from the 5th to the 2nd century B.C. Many inscriptions have been found at points along the Mediterranean shores—at the sites of the ancient Phoenician colonies, on Malta, in Carthage, and in other cities of the North African coast, as well as in Karetepe in Anatolia. The linguistic stage of Phoenician of the North African coast is called Punic and dates from the 5th to the 2nd century B.C.

Another important source of information are the transcriptions of Phoenician words into the scripts of other languages such as Egyptian, Akkadian and Hebrew. The most fruitful external source is to be found in classical literature. Phoenician words appear mostly in Greek literature; Punic in both Greek and Latin. Among the earliest are the names of the letters of the alphabet, which the Greeks took over together with the "Phoenician" alphabetic signs, perhaps in the 9th century B.C. A connected Phoenician discourse in transcription is found in *Poenulus* of Plautus (end of 2nd century B.C.). Since the "Phoenician" alphabet does not include vowels, these sources serve especially to give a picture of the vocalization of the language.

Ugaritic.—In Ras Shamra, on the coast of Syria, about seven or eight miles to the north of Latakia, another Semitic language was discovered in 1929. As a result of epigraphical and archaeological work, it soon became clear that the ancient name of the city of Ras Shamra was Ugarit, hence the name Ugaritic for that language. The history of Ugarit ended *c.* 1200 B.C. with the invasion of the Philistines. Ugaritic was written in an alphabetic cuneiform using about 30 simple signs which, on the whole, present single sounds rather than syllables or ideograms. A few tablets in Ugaritic script were also found in Palestine. The bulk of the texts is epical in content, and the language as well as the content throw considerable light on the Hebrew language and literature of the biblical period. The exact position of Ugaritic is not certain, some opinions being that it is "Early Hebrew," "Early Phoenician," "North Canaanite," an early dialect of Canaanite, an independent Northwest dialect or an Amorite dialect.

Amorite.—There is a term "MAR.TU" appearing in Sumerian texts of the 3rd millennium B.C. In the Akkadian texts of the 2nd millennium B.C., it appears as "Amurru." It is not yet definitely established whether at that time the term was to be limited to a "western" region or people or to a specific population element. Outside of Babylonia proper the term also appears in the texts of Mari (modern Tell el Hariri) on the Euphrates; these texts date from the 19th and 18th centuries B.C. In the Tell el Amarna letters of the second half of the 2nd millennium B.C., "Amurru" designates a district of Syria embracing the area of the Lebanon and Anti-Lebanon. The linguistic documentation of Amorite consists of proper nouns (with specific grammatical forms) and also of some words dispersed throughout the various Old Babylonian documents. These proper nouns and their morphological forms are interpreted as belonging to an "Amorite" dialect or, according

to some scholars, an "East Canaanite" dialect.

Aramaic.—The Aramaeans appear in the cuneiform texts of the 14th century as *aḫlamê*, later *aḫlamī armaya*. They extended their conquest from Mesopotamia to Syria-Palestine and northern Arabia. Aramaic superseded the various languages of the conquered countries and beginning with the 8th century B.C. it became the international language of the near east, as well as the official language of the Persian empire. The period of its greatest extension was from *c.* 4th century B.C. to the 7th century A.D. at which time it was supplanted by Arabic. Until the beginning of the Christian era there were no outstanding dialectal variations in the language called Common Aramaic. The language was then divided into West Aramaic and East Aramaic. The documents of Common Aramaic are various in kind. The inscriptions of principalities of Syria, such as the kings of Hamah between Damascus and Aleppo and of the kings of Samal found in Zinjirli to the north of Aleppo, date from the 9th to the 8th century B.C. The inscriptions of the Jewish colony of Elephantine (Aswan) in Egypt date from the 7th to the 4th century B.C. The Aramaic sections of the Bible (Ezra iv, 8–vi, 18; vii, 12–26; Daniel ii, 4–vii, 28, and isolated sentences) date from the 4th to the 2nd century B.C.

The dialects of West Aramaic are: Judeo-Aramaic, Samaritan, Palestinian-Christian, Nabataean, Palmyrene and Western Neo-Aramaic. Judeo-Aramaic is the dialect of certain Aramaic works found among the Dead Sea scrolls; of the Palestinian Targums, *i.e.*, the translations of the Bible into Aramaic; of the Palestinian Talmud compiled in the 5th century A.D.; and of some inscriptions. Samaritan is represented by the translation of the Pentateuch in the 4th century A.D., and by some other prayers and religious works. Palestinian-Christian is the dialect of sections of a translation of the Old and New Testaments, and of some religious texts translated by the Christian Melchites of Palestine in the 8th and 9th centuries A.D. Nabataean is the Aramaic dialect used by Arabs of Arabia Petraea and of Hauran to the east of Palestine, in the inscriptions found on the caravan roads through Sinai, northern Arabia, Transjordania dating from the 1st century B.C. to the 4th century A.D. Palmyrene is the dialect of the inscriptions of Palmyra, to the northeast of Damascus, dating mainly from the first three centuries A.D. Western Aramaic is still spoken in the mountainous regions of the Lebanon and Anti-Lebanon in the villages of Maʿlūla (Christian), and Baḫʿa and Ğubaʿdīn (Muslim).

East Aramaic includes Syriac, the Aramaic of the Babylonian Talmud, Mandaic, and Eastern Neo-Aramaic. Syriac was the language of Edessa (modern Urfa), the centre of Christianity at the end of the 2nd century. Since the 5th century A.D. owing to theological differences, Syriac-speaking Christians have been divided into Nestorians or East Syrians under the Persian sphere of influence, and Jacobites or West Syrians under the Byzantine sphere. These two groups became linguistically distinguished by certain differences in pronunciation. The greatest period for Syriac literature was between the 3rd and 7th centuries. (*See* SYRIAC LANGUAGE.) The Aramaic of the Babylonian Talmud, compiled in the 6th century, is another important dialect of the East Aramaic group. Mandaic is the dialect of a gnostic sect (also called Sabaeans) of lower Mesopotamia. An East Aramaic dialect is still spoken in the regions between Lake Urmia and Lake Van (by Nestorians, sometimes called Assyrians), in the district of Tur Abdin (Jacobites), and in the region north of Mosul. Catholic and Protestant missions have tried to develop the Mosul dialect as a literary language.

South Arabic.—*Epigraphic South Arabic.*—This language is represented by about 5,000 stone inscriptions found in the region of modern Yemen, Hadhramaut, and the Aden Protectorate. Since the tribe of Himyar of southern Arabia gained some importance before the Islamic period, the name "Himyarite" is also used for Epigraphic South Arabic. There are two main dialects in South Arabic: Sabaean and Minaean. The dialects of Qatabanite-Awsanite and of Hadhramaut are related to Minaean. The main difference between Minaean and Sabaean consists in the usage of the morphemes of the causative and of the independent and suffixed pronouns of the third person. These elements are *h* in the Sabaean group, and *s* in the Minaean group. Minaean inscriptions were also found in the northern Hejaz, in the neighbourhood of El ʿÖla and Tebuk. The Sabaean inscriptions, also discovered in the region of Aksum and of Yeha in Ethiopia, help reconstruct the political, cultural and religious history of the ancient kingdoms of "Arabia Felix," the most important being Maʿin, Saba, Qataban and Hadhramaut. The most ancient Minaean inscriptions are probably from the 8th century B.C., the Sabaean later.

Modern South Arabic.—There is a non-Arabic dialect cluster spoken in certain regions of southern Arabia between Hadhramaut and Oman. Conventionally called "Modern South Arabic," these dialects are: Mahri (spoken in Mahra); Botahari and Harsusi (close to Mahri); Shahari (also called Qarawi, Ehkili), east of Mahri; Kuria Muria (close to Shahari), a group of five islands off the coast of Arabia; and Sokotri (spoken on the island of Sokotra in the Gulf of Aden). Their relationship to Epigraphic South Arabic remains to be established. Since the Modern South Arabic dialects are surrounded by Arabic dialects, they are considerably influenced by them, especially in vocabulary.

For a description of Arabic, *see* ARABIC LANGUAGE.

Ethiopic.—The indigenous language of Ethiopia was not Semitic. Cushitic was the language group of the geographical area. It was some time in the 1st millennium B.C. that Semites (called Ḥabašat) from south Arabia entered Ethiopia. The region of their origin is not known nor is it known whether a single Semitic language was imported into Africa from south Arabia or several related tongues. The South Arabic speakers imported a Semitic language and a Semitic script, and it is this language that developed into Semitic-Ethiopic. Since the indigenous language group of Ethiopia was Cushitic, there was a very strong influence of Cushitic on the phonology, morphology, syntax and vocabulary of Semitic-Ethiopic. This influence is stronger in the south than in the north. The Semitic-Ethiopic languages are: Geez, Tigre, Tigrinya, Amharic, Argobba, Harari, Gurage and Gafat. From the descriptive point of view a division into North Ethiopic (including Geez, Tigre and Tigrinya) and South Ethiopic (including Amharic, Argobba, Harari, Gurage and Gafat) is appropriate.

Geez or Ancient Ethiopic is no longer spoken; it is the language of the liturgy. The oldest Ethiopic inscription, in unvocalized script, is that of Matara from the 3rd or 4th century A.D. The following inscriptions, in vocalized script, cover the period from the 4th to the 9th century. Between the 5th and 7th centuries the Bible was translated. No literary documents of the period from the 9th to the 13th century have come to light. Even though Geez ceased to be spoken sometime between the 10th and 12th centuries, it continued to be the literary language of Ethiopia. The classical period of Geez literature was between the 13th and 17th centuries. It is important to note that there is a traditional pronunciation of Geez used by the priests. This pronunciation, however, seems to be a reflection of the speech habits of the various vernaculars rather than any concrete evidence of the ancient pronunciation of Geez.

The languages closely related to Geez are Tigre and Tigrinya. Tigre is mainly spoken in the eastern and western lowlands of Eritrea, including the Massawa region and the Dahlak Islands in the east and up to the Kassala province and in the border regions of the Sudan in the west. The only literary documents are some religious texts printed by Swedish and Catholic missions. Tigrinya is spoken in the province of Tigre in northern Ethiopia. Tigrinya literature is still in its beginnings. As in the case of Tigre, various mission societies have printed biblical and religious texts in Tigrinya. In addition textbooks and other literary specimens are currently printed in the language.

Amharic (*q.v.*) is the national language of Ethiopia. Argobba is closely related to Amharic. It is spoken in the region of Ankober, to the north of Addis Ababa. It is decreasing in favour of Amharic. Argobba was also spoken to the south of Harar, but disappeared completely in favour of Galla, a Cushitic language. There is no literature in the language. Harari is spoken in the city of Harar in eastern Ethiopia. Because of its geographical position the Harari vocabulary has many Amharic and Galla loanwords. There are religious texts in Harari written in Arabic characters. Gurage is a dialect cluster spoken in the region of

Gurage, to the southwest of Addis Ababa. There are three main groups: (1) Eastern Gurage made up of Selti, Wolane, Ulbarag, Inneqor and Zway; (2) Western Gurage including Chaha, Eža, Ennemor, Endegeñ, Muher, Masqan and Gogot; (3) Northern Gurage with Aymellel as its only representative. Since Gurage is a Sidamo enclave, the vocabulary has a considerable number of Sidamo loanwords. There is no literature in Gurage other than a catechism in Chaha written in Ethiopic characters. Gafat was spoken in the region of the Blue Nile in the province of Godjam. The language disappeared completely in favour of Amharic and very few speakers remain.

GENERAL FEATURES

Phonology.—The consonant phonemes of proto-Semitic are: labials *b, p, m;* dentals *d, t, ṭ,* lateral (?) *ḍ;* interdentals *ḏ, ṯ, ṯ̣;* sibilants, *z, s, š, ṣ,* lateral (?) *ś;* velars *g, k, q,* spirants *ġ, ḫ;* liquids *l, n, r;* laryngeals and pharyngeals *ʼ, ʻ, h, ḥ;* semivowels *w, y.*

As can be seen, labials are not abundant. They are: *b, m, p.* In Hebrew-Aramaic *f* is a phonetic variant of *p;* indeed, *p* after a vowel becomes a spirant *f*. In South Semitic the original *p* became *f* in all positions. Ethiopic developed secondarily a *p* (beside *f*) and a glottalized *p̣*. There was no *v* in proto-Semitic.

The interdental series *ḏ, ṯ,* and *ṯ̣* remained only in Arabic and South Arabic. In the other languages the interdentals became either dentals or sibilants; this also occurred in some Arabic dialects. The correspondences for the ancient interdentals are as follows:

Proto-Semitic	Akkadian	Hebrew	Aramaic	Ethiopic
ḏ	*z*	*z*	*d*	*z*
ṯ	*š*	*š*	*t*	*s*
**ṯ̣*	*ṣ*	*ṣ*	*ṭ*	*ṣ*

The original laryngeal series (*ʼ, ʻ, h, ḥ*) is preserved only in some Aramaic dialects, ancient Hebrew, Arabic, South Arabic, and North Ethiopic.

Phonemes of uncertain pronunciation are *ḍ* and *ś;* they were perhaps laterals. They are preserved in Hebrew (*ś*), Geez (*ḍ*), South Arabic (*ḍ, s₂*), and in Arabic (*ḍ*).

The correspondences are as follows:

Proto-Semitic	Akkadian	Hebrew	Aramaic	Ethiopic	South Arabic	Arabic
ḍ	*ṣ*	*ṣ*	*ʻ(q)*	*ḍ*	*ḍ*	*ḍ*
ś	*š*	*ś*	*s*	*ś*	*s₂*	*š*

A characteristic feature of Semitic is the triadic system: voiced-voiceless-emphatic (mostly voiceless). Thus *d-t-ṭ; g-k-q; z-s-ṣ.* Ethiopic *b-p-p̣* is a secondary development.

Concerning the emphatic pronunciation there are two types: there is the emphatic-velarized type of Arabic (*ṭ, q, ṣ*), and the glottalized type of Ethiopic (*tʼ, kʼ, sʼ*). It is difficult to determine which was the original pronunciation of proto-Semitic.

In the vocalic system, proto-Semitic had the phonemic pattern of the vowels, *a, i, u* and *ā, ī, ū*. The various languages developed vocalic variants.

Morphology and Syntax.—*Roots.*—The meaning of a root lies in the consonants, the vowels serving to express shades of the basic meaning. This is unlike English, for instance, where *love, live* and *leave* have different meanings. In Semitic from the root *ktb* "write" are obtained *kataba* "he wrote," *kātib* "the writing one," *kutiba* "it was written," *kitāb* "book," the vowels expressing only shades of meaning without changing the basic meaning of the root. The Semitic root consists mainly of three radicals. There are, however, signs that there were more biradicals in ancient Semitic than at present. In the course of linguistic development many biradicals became secondarily triradicals. Ancient biradicals still preserved in the language are essential elements of the vocabulary, such as *ʼab* "father," *dam* "blood," *yad* "hand," and many more. Likewise many biradical verbs of the type *qām* "stand," and *mad(d)* "stretch" became perhaps only secondarily triradicals through the addition of a semivowel *w, y* (*qawama*) or the repetition of the last radical. A typical example of an ancient biradical "squeezed" into the triradical system is the Arabic diminutive *yudayy* "small hand" (of dialectal Arabic) from the biradical *yad* "hand" or the Ethiopic denominative *lab(b)awa* "understand" for *ləbb* "heart." In addition there are many roots whose basic meaning lies in the two radicals, as in *prq* "break," and *prṣ* "break," *prs* "separate," *pšr* "dissolve."

Nouns and Articles.—Proto-Semitic seems not to have had a definite article. It was formed secondarily in the various languages. The article is *al-* in Arabic, *ha-* (perhaps **hal-*) in Hebrew, a suffixed *-ā* in Aramaic, and so on. Akkadian has no definite article. While Geez has no definite article, the various modern Ethiopic languages employ various elements for the expression of the article.

Cases.—Proto-Semitic had three cases: a subject (nominative) case *-u,* an adnominal or possessive (genitive) *-i,* and a relational case mostly for the expression of the direct complement (accusative) *-a.* These case endings are also traceable in the plural. The case endings are completely preserved only in certain stages of Akkadian and in classical Arabic; the other languages preserve only traces of them.

Gender.—Semitic has a masculine and a feminine gender. The feminine is characterized by the suffixed morpheme *-(a)t* becoming *-ā* in the absolute state of Hebrew and *-a* in spoken Arabic. The feminine morpheme is most consistently used with the adjective. Special classes of nouns (such as parts of the body, geographical terms and others) are treated as feminine without having the feminine ending *-t.* Also words denoting female beings very often have no feminine ending (**ʼumm* "mother").

Number.—Proto-Semitic had three numbers: singular, dual and plural. The dual was originally used for parts of the body going in pairs. It is preserved in Akkadian, Hebrew, South Arabic and Arabic (where it extended to all nouns). Traces of the dual are to be found in the other languages. There are two kinds of plurals: an external plural and an internal plural. The external plural consists of the addition of a suffixed morpheme to the singular base. Its basic form for the masculine was probably *-ū* (or *-ī, -ā*) with the consonant addition *-n* or *-m,* the feminine plural morpheme is *-āt:* Arabic *malik* "king," pl. *malik-ūna;* Hebrew *meleḵ* "king," pl. *məlāḵîm;* fem. Arabic *malik-āt,* Hebrew *məlāk-ōṯ.* The internal plural consists of the vocalic change of the singular base; thus, for instance, *kitāb* "book," but *kutub* "books." The internal plural is preserved only in Arabic, South Arabic and in North Ethiopic. Traces of it are preserved in the other languages.

Numerals.—A puzzling feature in the usage of the numerals is the fact that the feminine form of the numeral is used with masculine nouns, while the masculine form of the numeral is used with the feminine nouns; thus, *ʼarbāʻā ʼaḥ-īm* "four brothers" (*ʼarbāʻ-ā* is the feminine form), *ʼarbaʻ ʼăḥāyōṯ* "four sisters."

Verbs.—The majority of the verbs are triradical (*ktb*) although there are some biradicals (*qām*) and quadriradicals (Omani *ḥarwas* "stamp"). The modern languages make extensive use of the quadriradicals, forming them either by total or partial repetition (1.2.1.2: Hebrew *gilgel* "roll"; or 1.2.3.3: Tigre *tbll* "envelop") or by inserting a liquid *n* or *l, r* into the triradical (Arabic *zanʻaq* "shout," root *zʻq;* Egyptian *ta-ʻarqal* "be bent," root *ʻql; ḥalbaṭ* "hit," root *ḥbṭ*).

The basic stem of a triradical verb in the perfect has the structure CaCaC- (C = consonant), as in Arabic *qatala* "he killed," and also CaCiC- and CaCuC-, as in Arabic *fariḥa* "he was joyful," *ḥasuna* "he was (is) beautiful." (In Hebrew the original *-i-* became *-e-* and *-u-* became *-o-,* thus *kāḇeḏ* "he was heavy," *qāṭon* "he was small".) Basically it would seem that the type CaCaC- expresses an action, be it transitive or intransitive (Hebrew *kāṯaḇ* "he wrote," Arabic *kaḏaba* "he lied"), whereas the types CaCiC- and CaCuC- express a state or condition that is completed (Hebrew *kāḇeḏ* "he was heavy," *qāṭon* "he was small") or uncompleted (*ḥāpeṣ* "he found delightful, he was delighted with a thing, he wished"). However, there are many exceptions to this principle.

Aspects or Tenses.—Proto-Semitic had aspects, not tenses. The aspects were: completed (perfect) and uncompleted (imperfect) action. Only at a later stage did the perfect come to express the past, while the imperfect expressed the present or future. Persons, numbers and genders were expressed in the perfect by

suffixes; in the imperfect by prefixes and suffixes. In Akkadian alone the completed and uncompleted actions are both expressed by forms with prefixes (*ikšud* "he has conquered," *ikaš(š)ad* "he conquers, he will conquer"), whereas duration ("the permansive") is expressed by a suffixed form (*kašd-ū* "they are, were, will be conquering"). Note that Ethiopic has the same syllabic structure of the prefixed forms but with different functions: *yĕnag(g)ĕr* "he speaks, he will speak," *yĕngĕr* "may he speak."

Stems.—An important feature of the Semitic verb is the formation of derived stems to express various modifications of the basic meaning. These stems are formed either by vocalic change (*qātala* against *qatala*), by gemination of the second radical (*qattala*) or by prefixed morphemes. The varieties in the formation of the derived stems in the various languages are considerable and no basic pattern can be given for proto-Semitic. An illustration will be taken from Arabic, but it should not be considered as representative of the general pattern of Semitic. Basic stem: *qaṭa'a* "cut." The intensive is formed by the gemination of the second radical: *qaṭṭa'a* "cut to pieces"; however, this form also expresses occasionally a causative: *ḥassana* "embellish," from *ḥasuna* "be pretty." The conative meaning is formed by changing the vowel *a* of the first radical into *ā*: *kātaba* "correspond" against *kataba* "write." The causative is formed by a prefixed *'a-*: *'a-ǧlasa* "cause to sit down, seat," from *ǧalasa* "sit down"; the other languages express the causative either by *'*, *h* or *s*, *š*. The reflexive-passive of the basic stem is formed either by prefixed *n* or by infixed *t*, from the intensive and conative it is formed by a prefixed *t-*, from the causative it is formed by a prefixed *st-*: *in-qaṭa'a* "be cut" (from *qaṭa'a*), *iǧ-ta-ma'a* "come together, be united" (from *ǧama'a* "gather"), *ta-qaṭṭa'a* "be cut to pieces" (from *qaṭṭa'a* "cut to pieces"), *ista-ḫbara* "inquire, take information" (from *'aḫbara* "inform"). The passive meaning is also formed in Arabic and in Hebrew (but not in the other languages) by an internal vocalic change: *kutiba* "it was written" against *kataba* "he wrote." The reciprocal is formed by *ta-* added to the basis of the conative: *ta-qātala* "fight with one another."

Vocabulary.—A short list of common words will illustrate the closeness of relationship.

TABLE.—*Common Words*

English	Akkadian	Hebrew	Aramaic	Ugaritic	Ethiopic	Arabic
brother	*aḫu*	*'aḥ*	*'aḥā*	*aḫ*	*'ĕḫᵘ*	*'aḫ*
master	*bēlu*	*ba'al*	*ba'lā*	*b'l*	*bā'ĕl*	*ba'l*
dog	*kalbu*	*keleḇ*	*kalbā*	*klb*	*kalb*	*kalb*
fly	*zumbu*	*zəḇūḇ*	*dabbāḇā*		*zĕmb (Amh.)*	*ḏubāb*
seed	*zēru*	*zera'*	*zar'ā*	*dr'*	*zarĕ'*	*zar'*
head	*rēšu*	*rō(')š*	*rēšā*	*riš*	*rĕ'ĕs*	*ra's*
eye	*ēnu*	*'ayin*	*'aynā*	*'n*	*'ayn*	*'ayn*
tongue	*lišānu*	*lāšōn*	*liššānā*	*lšn*	*lĕsān*	*lisān*
tooth	*šinnu*	*šen*	*šənānā*		*sĕnn*	*sinn*
sky	*šamū*	*šāma-yim*	*šəmayyā*	*šm(y)m*	*samāy*	*samā'*
night	*līlātu*	*laylā*	*lelyā*	*ll*	*lelīt*	*layla*
water	*mū*	*ma-yim*	*mayyā*	*my*	*māy*	*mā'*
house	*bītu*	*bayiṯ*	*baytā*	*bt*	*bet*	*bayt*
peace	*šalāmu*	*šālōm*	*šəlāmā*	*šlm*	*salām*	*salām*
name	*šumu*	*šem*	*šəmā*	*šm*	*sĕm*	*ism*

Scripts.—There are three scripts used in the Semitic languages: cuneiform writing, North Semitic writing and South Semitic writing. Cuneiform writing was used in Akkadian. It seems that the invention was that of the Sumerians of Mesopotamia and it was from them that the Assyrians and Babylonians took over the script. In the beginning the symbols were pictorial. At a later stage the symbols were used as word-signs (or ideograms) representing also abstract ideas; so, for instance, the solar disc came to indicate the idea of "day" and "time." As a further development the word-signs represented the phonetic value of words without any regard to their meaning as pictures.

Thus a syllabary was produced without achieving, however, an alphabetic system.

Cuneiform signs were also used in Ugaritic for which a particular cuneiform alphabet was developed, not dependent on the Sumerian-Assyrian-Babylonian. The symbols represented only consonants with the exception of three *alephs* with vowels (*'a*, *'i-'e*, *'u-'o*).

The North Semitic script has two main branches: the Canaanite and the Aramaic. The offshoots of the Canaanite branch are "Early Hebrew" and "Phoenician." (For the "Early Hebrew" script, *see* HEBREW LANGUAGE.) The script of the Moabite stone is closely related to Early Hebrew writing, the Samaritan alphabet is a descendant of Early Hebrew script.

The earliest written document in Aramaic is from the 9th century B.C. In the second half of the 1st millennium B.C. it became the most widespread script of the entire near east. The Semitic offshoots of the Aramaic alphabet are: Square Hebrew (which developed into the modern Hebrew script), Nabataean-Sinaitic-Arabic (with its two main branches of Naskhi and Kufic), Palmyrene, Syriac-Nestorian and Mandaean.

All these alphabets express only consonants. The vocalic symbols of Syriac, Arabic and Hebrew were probably introduced in the 8th century A.D.

South Semitic Alphabet.—The South Semitic alphabet was used for Epigraphic South Arabic and for the North Arabic inscriptions of Thamudenic, Lihyanite and Safaitic. The South Arabic alphabet passed into Ethiopia in the 1st millennium B.C. But whereas the South Arabic alphabet is consonantal, the Ethiopic alphabet is syllabic, that is, there is a single symbol for the consonant with vowel. The problems of the origin of the South Semitic alphabet and the invention of the Ethiopic vowels are still unsolved.

SEMLER, JOHANN SALOMO (1725–1791)

SEMLER, JOHANN SALOMO (1725–1791), German Lutheran theologian who developed the principles of textual criticism of the Bible and the idea of a history of the Bible canon, was born at Saalfeld, Thuringia, on Dec. 18, 1725. The son of a pastor, he grew up in pietistic surroundings which left him with a lifelong aversion to Pietism. At Halle University he became the disciple, later the assistant, and finally the literary executor of the orthodox rationalist S. J. Baumgarten. After holding positions at Coburg and the University of Altdorf, Semler became professor of theology at Halle in 1753, succeeding Baumgarten in 1757 as head of the theological faculty. He died on March 14, 1791.

Semler's lectures and copious writings on biblical criticism provoked fierce opposition. He broke away from orthodox theology in evolving an undogmatic, strictly historical interpretation of Scripture, challenging the idea of verbal inspiration. His distinction between religion and theology was based on Luther's distinction between the Word of God and Scripture; revelation he understood purely as the message of truth related to man as a natural being. Despite contemporary accusations, Semler was no rationalist, in that faith remained essential for him to an understanding of religion; he proved his position by his reply (1779) to the deistic *Wolfenbüttel Fragments* of H. S. Reimarus (*q.v.*; *see* also LESSING, GOTTHOLD EPHRAIM).

On the practice of religion, however, Semler's ideas were by no means clear. He attempted to draw a distinction between private and public religion, the former to be a matter of private conscience, the latter a question of public order. This led to his unfortunate defense of the Prussian government's reactionary *Religionsedikt* (1788), an attack on enlightened tendencies in the church.

SEMMELWEIS, IGNAZ PHILIPP (1818–1865), Hungarian physician, whose influence on the development of knowledge and control of infection was cited by Joseph Lord Lister, the father of modern surgery: "Without Semmelweis my achievements would be nothing. To this great son of Hungary Surgery owes most." He was born at Buda on July 1, 1818, and educated at the universities of Pest and Vienna, where he attracted the attention of Joseph Skoda and Karl von Rokitansky. He graduated M.D. at Vienna in 1844 and was appointed assistant in the first obstetric clinic under Johann Klein.

BY COURTESY OF THE LIBRARY OF MEDICAL HISTORY, BUDAPEST

IGNAZ PHILIPP SEMMELWEIS, PAINTING BY A. CANZI, 1857

Puerperal infection was the scourge of maternity hospitals throughout Europe. Although most women delivered at home, a few women who had to seek hospitalization because of poverty, illegitimacy or obstetrical complications faced a mortality rate of 3% to 25% because of childbed fever, or puerperal infection. Although its cause was unknown, it was thought that it was induced by overcrowding, poor ventilation, the onset of lactation or a "miasma."

Semmelweis, during his student days, became interested in this great killer of young mothers and as an assistant he proceeded to investigate its cause despite the serious objections of Klein, the chief of the maternity. Two or three times as many women who delivered in the first division died of childbed fever as those who delivered in the second division, although the two maternities were identical with the exception that students were taught in the first and midwives in the second. Semmelweis reasoned that perhaps the students carried something to the patients they examined during labour. The death of his friend Jakob Kolletschka, a pathologist, from a wound infection incurred during the examination of a woman who died of puerperal infection, and the similarity of the findings in his friend and in the women who died of puerperal infection, provided Semmelweis' first breakthrough. He concluded that students, who came directly from the dissecting room to the maternity, carried infection from mothers who had died of this dread complication to healthy mothers they examined during labour.

Semmelweis promptly instituted thorough washing of the hands with soap and water prior to examination of a woman in labour and later introduced ablutions with chlorinated lime. The mortality of the first division promptly dropped below that of the second. The outstanding success of this simple measure failed to impress Klein, who, blinded by ignorance, vanity, or jealousy, restricted Semmelweis' activities, underhandedly prevented his promotion to assistant professor, and drove him from Vienna.

In 1850 Semmelweis was appointed obstetric physician in the maternity department at Pest, where his ideas promptly reduced the high maternal mortality to 0.85%. He developed a private practice among influential people, married, and seemed reasonably content. However, he continued to be plagued by the failure of the profession to accept his doctrine and thereby save the lives of countless young women.

He died on Aug. 17, 1865, from a wound of the right hand, a victim of the very disease for which he had sacrificed his health, fortune, and peace of mind.

Semmelweis' chief publication was *Die Ätiologie, der Begriff und die Prophylaxis des Kindbettfiebers* (1861), Eng. trans. by F. P. Murphy.

BIBLIOGRAPHY.—Biographies by Hegar (1882), Bruck (1887), Duka (1882), Grosse (1898), and Schürer von Waldheim (1905). *See* also the interesting medical novel, *The Cry and the Covenant* (1954), by Morton Thompson, which depicts the life of Semmelweis.

(M. E. Ds.)

SEMMERING, Austria, the most easterly and lowest (3,215 ft. [980 m.]) of the great Alpine passes. In the watershed dividing the Mur and Leitha drainage basins, it facilitates Vienna's communications with Yugoslavia via Styria (Steiermark), with Italy via Carinthia (Kärnten), and via the upper Enns Valley with Innsbruck. Since the ancient routes skirted the Alps in the east, the Semmering remained unimportant until the foundation of the hospice (Spital am Semmering) in 1160 and the union of Austria and Styria. The first road was built in 1728 and rebuilt in 1839–42. The Semmering railway (1848–54) was the first mountain railway in the world. It passes about 282 ft. (86 m.) below the summit of the pass through a tunnel nearly one mile long. A second parallel tunnel was inaugurated in 1952. (K. A. S.)

SEMMES, RAPHAEL (1809–1877), U.S. naval officer who commanded the Confederate ship "Alabama" during the American Civil War, was born in Charles County, Md., on Sept. 27, 1809. He was appointed midshipman in the Navy in 1826, and while waiting for orders studied law and in 1834 was admitted to the bar. In the war with Mexico, Semmes was active in superintending the landing of General Scott's troops at Veracruz in March 1847, and later, as volunteer aid to General Worth, took an active part in the battles of the valley of Mexico. These experiences were interestingly described in his books *Service Afloat and Ashore During the Mexican War* (1851) and *The Campaign of General Scott in the Valley of Mexico* (1852). In 1855 he was promoted to commander and afterward was made naval secretary of the Lighthouse Board at Washington, in which service he was when the Civil War broke out. When Alabama, his adopted state, seceded, he resigned his commission and received an appointment of the same rank in the Confederate Navy. He fitted out the packet "Sumter," in which he captured as many as 17 Northern merchant vessels, chiefly along the South American coast. Later he commanded the "Alabama," a 1,016-ton ship built in England for the Confederacy, with which he made a series of daring and successful cruises lasting two years. Finally, he met the Northern ship "Kearsarge" in the English Channel, and after a 70-minute battle was forced to surrender. Twenty minutes later the "Alabama" sank and Semmes was rescued by an English yacht.

When Semmes returned home he was commissioned rear admiral and assigned to the Confederate fleet in the James River. When Richmond was captured he blew up his ships and, with his men, joined the army of General Johnston. When Johnston surrendered, Semmes returned to his home in Mobile and opened a law office, to which practice he devoted the greater part of the rest of his life. He died on Aug. 30, 1877.

In addition to his books on the Mexican War, he wrote *The Cruise of the Alabama and the Sumter* (1864) and *Memoirs of Service Afloat During the War Between the States* (1869).

SEMNAN (SAMNAN), the chief town of a *shahrestan* (district) and of the general governorship of Semnan-Damghan in northern Iran, lies at an elevation of 3,740 ft. (1,140 m.) on a large, mostly desert plain at the southern foot of the Elburz Mountains, and 145 mi. E of Teheran on the main road to Meshed. Pop. (1956) 29,036. In the town are a minaret (12th century) with rich ornamentation of raised brick and remains of a rebuilt mosque of the same period. Several large *Hosseiniyehs* (*Husainiyehs*, places of worship of Husain; *see* HASAN AND HUSAIN) are conspicuous. Semnan is a thriving market centre for the agricultural products of the district, chiefly grains, cotton, and tobacco. Besides a lively bazaar, there is some textile industry and carpet making. There are sulfur deposits 20 mi. (32 km.) SE of the town, and in 1959 oil was discovered at Khurian (formerly a Soviet-held concession), 25 mi. (40 km.) S. The town is also linked by rail with Teheran and Meshed.

Semnan is mentioned by Ptolemy as Samina, and cited by the Oriental geographers for the rivulets running through its streets, for the making of soft cotton stuffs, and for its sweet paste made from almonds and figs. The town was the administrative headquarters of the former province known as Semnan wa Damghan, which became part of the 2nd *ostan* (province) of Mazanderan in 1938. In 1961 Semnan-Damghan was formed into a separate general-governorship. *See* MAZANDERAN. (H. Bo.)

SEMO SANCUS DIUS FIDIUS, an obscure Roman deity; a god Fisios or Fisovios Sancios was also worshiped in Umbria, and appears to be the same. He had a temple at Rome on the Quirinal, in which was an ancient statue of a woman, said to be Gaia Caecilia, or Tanaquil, wife of Tarquinius Priscus. His functions are very obscure. The four parts of his name seem to be connected respectively with seed (*semen*), purity or holiness (*sancus* and *sanctus* are from the same root), Jupiter (or simply brightness, or celestial nature; Dius, root *Div*), and faith (*fides*). Hence perhaps "the spirit of sowing (or seed), pure, Jovian (or bright, or celestial), faithful." Of his ritual we know only that oaths by him were taken in the open air, the formula being *medius fidius, cf. mehercule*, "by Hercules"; that there was an opening in the roof of his temple; and that certain disks of metal were kept in the temple. The first two facts perhaps suggest a sky god, but we know that certain deities undoubtedly not celestial (for example, Terminus, the spirit of boundaries) had similar ritual. The disks might possibly be solar symbols. On the whole, the balance of the very scanty evidence is rather in favour of supposing him to be a god of the sky, perhaps connected, as Wissowa supposes, with Jupiter, who had power to influence seed corn (by sending rain in season?) and, being able to see what went on in the world, was a natural witness to solemn oaths. The ancients, wrongly supposing the last two members of his name to signify "son of Zeus," identified him with Hercules, an error which some moderns also have fallen into.

SEMPER, GOTTFRIED (1803–1879), German architect and writer on art, who initiated the neo-Renaissance style, was born in Hamburg, on Nov. 29, 1803. He studied in Munich and Paris and practised architecture in Dresden from 1834 until 1848 when, because of revolutionary activities, he was forced into exile to Paris and London. He headed the architecture department of the Zürich Polytechnikum (1855–71) and between 1871 and 1876 participated in the rebuilding of Vienna. His work marks the transition away from the classicism of his friend Karl Schinkel. As an eclectic, he achieved powerful solutions. Among his main works were the Dresden opera house (1837–41, rebuilt 1871–78); the Zürich Polytechnikum (1858–64); and with Karl von Hasenauer, the Vienna Burgtheater (1874–88) and the two imperial museums in Vienna (1872–81). In his influential writings, principally *Der Stil in den technischen und tektonischen Kunsten* (1860–63), he stressed a rational interpretation of techniques as a source of style, recommending colour in decorative arts and architecture. He died in Rome on May 15, 1879.

His nephew KARL SEMPER (1832–1893) was a zoologist, noted for his studies of Philippine fauna. (A. K. P.)

SEMPILL OF BELTREES, a family of Scottish poets. SIR JAMES (1566–1626) was born in 1566 and brought up with the young King James VI, and like him was tutored by George Buchanan. He went to St. Andrews university, and became ambassador to England (1599) and to France (1601). He was knighted in 1600 and died at Paisley in Feb. 1626. His writings include a few controversial tracts, but he is remembered rather for his satirical poem *The Pack-mans Pater Noster*, an antipapal dialogue between a pedlar and a priest, written in English in rhyming couplets. This poem, when reprinted in 1669, contained additions by his son ROBERT (*c.* 1595–*c.* 1665), who was born *c.* 1595, was educated at Glasgow university, fought for the royalists during the Great Rebellion and wrote the elegy on Habbie Simson, "The Life and Death of the Piper of Kilbarchan." This humorous poem in Scots was included by James Watson in his *Choice Collection* (1706) and its fame was assured when Allan Ramsay called its metre "Standart *Habby*" and used it himself in several poems. "Standart *Habby*" was later known, after its greatest exponent, as the Burns stanza. Robert Sempill died *c.* 1665. Little is known of FRANCIS (*c.* 1616–1682), son of Robert, except that he was born *c.* 1616, was made sheriff-depute of Renfrewshire some time before 1677 and died at Paisley on March 12, 1682. He is reputedly the author of some popular and entertaining Scots poems, "The Blythsome Bridal," "Maggie Lauder" and "Hallow Fair."

An earlier ROBERT SEMPILL (*c.* 1530–1595), also a poet, has no proved connection with the Sempills of Beltrees. He was born *c.* 1530 and appears to have held some office at the Scottish court, being mentioned in the treasurer's accounts in 1568. From the evidence of his poems he was probably present at the sieges of Leith (1560) and of Edinburgh (1573). He probably died in 1595.

Sempill wrote many vigorous, bitter and often coarse satirical Scots poems on religious and social topics of the day; his work is violently Protestant and suited to his description of himself as "rakles [reckless] Robert."

BIBLIOGRAPHY.—For the earlier Robert Sempill see *The Sempill Ballates*, ed. by T. G. Stevenson (1872) and *Satirical Poems of the Time of the Reformation*, ed. by J. Cranstoun, Scottish Text Society, 2 vol. (1891–93). For the other Sempills see *The Poems of the Sempills of Beltrees*, ed. by J. Paterson (1849) and G. Eyre-Todd, *Scottish Poetry of the 17th Century* (1895). (E. G. M.)

SENA, an Indian dynasty ruling in Bengal in the 11th and 12th centuries. Their ancestors came from the south and became petty rulers in southwestern Bengal early in the 11th century, as tributaries of the Pala (*q.v.*) dynasty. Hemantasena, in the mid-11th century, became independent and assumed imperial titles. His successor, Vijayasena (reigned *c.* 1095–1158), built an empire on the ruins of that of the Palas, gaining control of all Bengal and north Bihar. The next ruler, Vallalasena, was the author of religious literature and is the reputed founder of the Bengali system of hypergamy (*i.e.*, socially "upward" marriage of women); he reestablished the caste system where it had become lax owing to Buddhist influence under the Palas. The last important Sena king, Lakshmanasena (*c.* 1178–*c.* 1205), after military successes, became a great patron of literature; the poets Jayadeva and Dhoyi wrote at his court at Nadia. In 1202 Lakshmanasena was expelled from Nadia by the Turkish chief Mohammed Bakhtiyar Khalji and died about three years later. Sena kings continued to rule in east Bengal for some decades, but the main political power in Bengal passed to the Muslims.

There was a marked revival of orthodox Hinduism under Sena rule.

See R. C. Majumdar (ed.), *The History of Bengal*, vol. i (1943). (A. L. BA.)

SÉNANCOUR, ÉTIENNE PIVERT DE (1770–1846), French author whose best-known work, *Oberman* (2 vol., 1804), marks him as a precursor of the Romantic movement. He was born in Paris in November 1770, the son of a *contrôleur des rentes*. His father intended him to be a priest, and in 1789, to avoid entering the seminary of Saint-Sulpice, he went to Switzerland, where in September 1790 he made a rash, and eventually unhappy, marriage with a Mlle Daguet. At the Revolution his name was included on the list of emigrants and he did not return permanently to Paris until 1803. In 1795 *Aldomen; ou, le bonheur dans l'obscurité*, an early draft of *Oberman*, was published. *Rêveries sur la nature primitive de l'homme* (1799) contains passages of impassioned description of the nature of man. *Oberman* (in later editions spelled *Obermann*) consists of a series of reveries in letter form written by a solitary in a valley in the Jura. The book, which was to a great extent inspired by Jean Jacques Rousseau (*q.v.*) was edited by Sainte-Beuve (1833) and George Sand (1852), and was praised for its poetic interest in nature and in man by Matthew Arnold (*Essays in Criticism*, Second Series, 1888; the essay, "Obermann," in the *Academy*, Oct. 9, 1896). It had considerable influence in France (*see* FRENCH LITERATURE: *The Revolution and the 19th Century*) and in England, and with Chateaubriand's Romantic novel *René* (published as part of the *Génie du christianisme*, 1802) it opened the way to a new type of writing, the main characteristic of which was a pervasive melancholy. Sénancour also wrote a treatise on love, *De l'Amour consideré dans les lois réelles et dans les formes sociales de l'union des deux sexes* (1805); and a meditative work, *Libres méditations d'un solitaire inconnu* (1819). In 1833 his other novel in letters, *Isabelle*, was published. He died at Saint-Cloud on Jan. 10, 1846.

BIBLIOGRAPHY.—*Rêveries sur la nature primitive de l'homme*, ed. by J. Merlant (1910); *Oberman*, reprinted from the 1st ed., ed. by A. Monglond, with a critical explanation entitled *Journal intime d'Oberman*, 3 vol. (1947). *See* also J. Merlant, *Sénancour* (1907); G. Michaut, *Sénancour, ses amis et ses ennemis* (1909); A. Monglond, *Vies préromantiques* (1925), *Jeunesses* (1933).

SENATE, ROMAN, the most permanent element in the Roman constitution. The Latin word *senatus* suggests an assembly of old men (from root *sen-*, as in *senex,* old), originally the heads of the chief families. The word corresponds with the Greek *gerousia* (*q.v.*), the name of the council of elders at Sparta. The Athenian Areopagus (*q.v.*) may in some ways be compared to the Roman Senate.

Origins.—The Roman authorities ascribe the origin of the Senate to Romulus, who chose 100 of the best of his subjects to form an advisory council. In 509 B.C. it contained 300 members and a distinction existed within it between *patres maiorum gentium* and *minorum gentium,* the heads of the greater and the lesser families. Throughout the monarchical period the Senate consisted entirely of patricians. Probably the rise in the number of the senators was due to the incorporation of fresh elements into the patrician community, the new clans comprising *gentes minores* (lesser families). The appointment of senators depended entirely upon the king, who possibly might change his advisers during his reign; a new king could certainly abstain from summoning some of those convened by his predecessors. The powers of the Senate at this time were very indefinite.

Republican Period.—With the abolition of monarchy the Senate became the advisory council of the consuls (*see* CONSUL), meeting only at their pleasure, and owing its appointment to them; it remained a power secondary to the magistrates. Few, if any, plebeians were introduced into the Senate at this time, but the existence of an elderly plebeian senator is attested in 401 B.C. In one respect, substitution of consuls for kings tended to the subordination of the chief magistrates to the Senate. The consuls held office only for one year, while the Senate was a permanent body; in experience and prestige, its individual members were often superior to the consuls of the year. The magistrate would seldom venture to disregard the advice of the Senate, especially as he himself, in accordance with steadily growing custom, would become a senator at the end of his year of office. It was probably in their capacity of former magistrates that plebeians first entered the Senate. Of the two powers which the Senate inherited from the monarchy, the interregnum and the *patrum auctoritas* (senatorial claim to ratify), the first came to be exercised only rarely; for if either consul existed, interregnum could not be resorted to. The *patrum auctoritas,* however, developed into a definite right claimed by the patrician senators to give or withhold their consent to any act of the *comitia* (*q.v.*). The influence which it had long exercised over foreign policy increased the importance of the Senate in a period of constant warfare with the peoples of Italy. But in the early Republic the Senate remained an advising body and assumed no definite executive powers.

In the last two centuries of the Republic, a great change took place. The Senate became a self-perpetuating, automatically constituted body, independent of the annual magistrates, a recognized factor in the constitution, with extensive powers. About 312 B.C. the selection of senators (*lectio senatus*) was transferred from the consuls to the censors (*q.v.*), who normally chose former magistrates. In 81 B.C. Sulla secured an automatic composition for the Senate by increasing the number of quaestors to 20, and enacting that all former quaestors should pass at once into the Senate (*see* QUAESTOR).

The Senate's powers had then extended far beyond its ancient prerogatives. The power to appoint an interrex had fallen into practical disuse, and the power to ratify decisions of the *comitia* had become a mere form by the last century of the republic. But the Senate had acquired more effective control through the observance of certain unwritten rules regulating the relation between Senate and magistrates, to whom it formally gave advice. It became the chief governing body in Rome and tendered advice on home and foreign policy, on legislation, and on financial and religious questions. It acquired the right to assign duties to the magistrates, to determine the two provinces to be entrusted to the consuls, to prolong a magistrate's period of office (*prorogatio imperii*), and to appoint senatorial commissions to help magistrates to organize conquered territory. Its earlier influence upon foreign policy developed into a definite claim to conduct all negotiations with a foreign power, although the formal declaration of war and ratification of treaties were referred to the people. It often acted as arbitrator in disputes among Italian communities, provincials, or client-states.

Though individual senators after 218 B.C. were debarred from trading, the control of finance was in the Senate's hands. Three circumstances had combined to bring this about. The censors, who were only occasional officials, were entrusted with the leasing of the public revenues; the Senate could order them to redraft contracts. The details of public expenditure were entrusted to the quaestors, young and inexperienced magistrates whom the Senate could guide. Third, the general control exercised by the Senate over provincial affairs implied its direction of the income derived from the provinces. It also claimed the right of granting occupation and decreeing alienation of public lands. Every branch of state finance was therefore in its hands: it controlled revenue and expenditure and supervised the treasury (*aerarium*). In matters of criminal jurisdiction, the Senate claimed the right, in times of crisis, to set free by its decree the full powers of coercion that were contained in the *imperium* (supreme administrative power) of a magistrate but that were limited normally in capital cases by laws of appeal. The first certain use of this right, which amounted to a declaration of martial law, concerned Gaius Gracchus; the last was in 40 B.C.

This ever-widening influence and power of the Senate was challenged by tribunes (*see* TRIBUNE) from the time of Tiberius Gracchus onward (133 B.C.); and more particularly by the military leaders, from Marius onward, who pitted their *imperium* against the *auctoritas* of the senate. Despite the short-lived attempt of Sulla to reinstate the Senate's ascendancy, the Republic collapsed under these repeated blows at the authority of the Senate. As a result of the civil war the number of senators, which Sulla had raised to 500 or 600, was seriously depleted. Julius Caesar revised the list and increased the Senate to 900, naturally filling it with his own supporters. This reflects the practice by which the early magistrates had chosen their own body of councilors. The composition of the Senate thus underwent a considerable change: few of the senators who had opposed Caesar survived; the new senators included many *equites* (*q.v.*) and municipal Italians and even a few provincials from Gaul.

The Empire.—Since Augustus officially "restored the Republic" (27 B.C.), it was essential to preserve the prestige of the Senate, which came to be regarded in the early principate as the representative of republican institutions. With this object, and also in order to provide an adequate body of administrators, Augustus established a *senatorius ordo* (senatorial order), limited to men of personal integrity, who had completed a term of military service and who possessed a minimum property qualification. From this order, men who had served in the army and had then held one of the minor magistracies could enter the Senate at the age of 25 through the quaestorship. The *senatorius ordo* tended to become a hereditary body because normally only sons of senators could become senators.

Since the election of magistrates was transferred from the people to the Senate, to a large measure under Augustus and completely under Tiberius, the Senate became a self-recruiting body, whose numbers were reduced to 600. The emperor could influence the quaestorian elections; he also had the right of appointing as new members of the Senate men who had not been magistrates. Most of the important offices in the state were filled by senators, whose careers depended largely on the good will and confidence of the emperor.

Augustus did not share his basic power with the Senate, but he did allow it to co-operate with him in most of the spheres of government. It was left at the head of the ordinary administration of Rome and Italy, together with those provinces which did not require any military force or present special administrative difficulties. It continued to administer the *aerarium* but was soon overshadowed by the emperor, who allowed it to supervise the copper coinage alone. The Senate received judicial functions and for the first time became a court of law, competent to try cases of extortion in the senatorial provinces (for these *see* PROVINCE,

ROMAN: *The Principate*) and with criminal jurisdiction over offenses by its own members. The legislative powers of the *comitia* became very gradually extinct, and *senatus consulta* (decrees of the Senate) came to take the place of *leges* in ordinary matters although they did not at first acquire full recognition as laws. On the other hand, the Senate lost all its control of foreign policy, and though it was occasionally consulted by the emperor it was entirely subordinate to him in this department. The emperor could convene and preside over the Senate, his report (*relatio*) taking precedence; he was also *princeps senatus* (*i.e.*, his name headed the list of senators). Relations varied with the different emperors, but although recognition by the Senate provided formal acceptance of an emperor's claim to rule, the Senate in practice lost independence of action and freedom of discussion declined.

The number of Italian and provincial senators increased (especially under Vespasian), but the Italians were not outnumbered by the provincials until after the reign of Septimius Severus. At first the provincials came predominantly from Spain and Narbonese Gaul, but later there were more Asians and Africans. Under Gallienus senators lost the right to command legions and much of their part in provincial administration. Under Constantine they were virtually amalgamated with the *equites*, who had benefited from these changes. The number of the new senators rose in the 4th century to about 2,000. That the Senate was still regarded as a representative and necessary part of the constitution is shown by Constantine's creation of a duplicate Senate in Constantinople.

The most important senators were the great landowners throughout the empire, whose position became almost feudal. A great number of them failed to leave their estates to attend meetings, and the Senate often acted—as it had in the early days of the Republic—merely as a town council for Rome, under the chairmanship of the prefect of the city. Senators were free from municipal burdens but not from all taxation. Many of the great senatorial landowners were men of culture who represented Roman civilization amid increasing barbarism and tried to uphold paganism in Italy. In the 5th century, however, some of them helped the barbarian leaders against the imperial authority. In the 6th century the Roman Senate disappears from view: it is last mentioned in A.D. 580. *See* also ROMAN HISTORY.

SENDAI, the capital and largest city (pop. [1960] 452,272) of Miyagi Prefecture, Japan. Site of a great castle, Sendai enjoyed prosperity during the feudal period as headquarters of the powerful Date Clan. The largest city and commercial centre for northern Honshu, it is also the regional seat of federal administrative agencies. It is a rail centre but depends upon an outport, Shiogama, in the southwestern corner of Matsushima Bay, for ocean contacts. The relatively few Sendai manufactures are primarily for local consumption; a small industrial zone is developing around the Shiogama port facilities. Tohoku University is outstanding among Sendai's many schools. (J. D. EE.)

SENEBIER, JEAN (1742–1809), Swiss pastor remembered for his contributions to the knowledge of photosynthesis, was born at Geneva on May 6, 1742. The observation by C. Bonnet of bubbles of oxygen on the leaves submerged in aerated water induced Joseph Priestley, Jan Ingenhousz, and Senebier to carry out a series of experiments showing the influence of light on vegetation. Senebier reported his conclusions in his most important work, *Physiologie végétale*, 1800.

Senebier proved that the presence of carbonic acid is a deciding factor in the development of oxygen by green plants in sunlight and that with decomposition of carbonic acid oxygen is liberated. Thus he was first to give a connected view of the whole process of vegetable nutrition. He died at Geneva on July 22, 1809. (V. C. AS.)

SENECA, ANNAEUS (*c.* 55 B.C.–*c.* A.D. 39), of Corduba (Córdoba) in Spain, commonly known as Seneca the Elder to distinguish him from his more famous son Lucius Annaeus Seneca, wrote an account of certain Roman rhetoricians of the age of the emperor Augustus. Little is known of his life except that he visited Rome at least twice, probably for long periods.

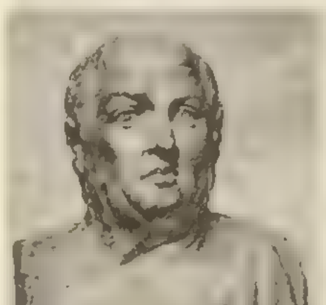
His book is concerned with the practitioners of declamation. "Declamations," originally speeches delivered privately for practice or rehearsal, had been transformed by Seneca's time into a public entertainment. They were of two kinds: those based on themes drawn from mythology or history, such as "Should the 300 Spartans at Thermopylae run away?," known as *suasoriae* because they purported to offer advice, and *controversiae*, fictitious legal cases based on some stated "law," itself either fictitious or an extremely simplified version of some existing enactment.

Seneca, who shows a fine and balanced literary judgment, disapproved of the artificial cleverness, often degenerating into absurdity, of many declaimers, but nevertheless produced a record of their work, with abundant quotation. Only about half of his book, which is entitled *Oratorum sententiae divisiones colores*, is extant; an epitome, written probably in the 4th century, covers most of the remainder. *Sententiae* were brief pointed utterances, *divisiones* the subdivisions of the subject matter, and *colores* the "slants" which the declaimers gave to the prescribed facts of their themes, so as, for instance, to make apparently unfavourable circumstances tell in favour of an imaginary defendant.

The perverse ingenuity of most of Seneca's quotations soon palls. The literary fashion which they record is interesting only from the harm it did to some major writers such as Ovid. Seneca's work is, however, valuable for the introductions to the books into which it is divided and for the comments interspersed throughout, which give much important and entertaining information about literary circles in Augustan Rome and also preserve several interesting passages which have not otherwise survived, for instance, various accounts, including Livy's, of the death of Cicero.

Edward with Eng trans (1928). *See* also H. Bornecque, *Les Déclamations et les déclamateurs d'après Sénèque le père* (1902); S. F. Bonner, *Roman Declamation in the Late Republic and Early Empire* (1949). (A. E. DO.)

SENECA, LUCIUS ANNAEUS (*c.* 4 B.C.–A.D. 65), Roman statesman, philosopher, satirist, and tragedian, one of the most important Latin writers of the 1st century A.D., was born at Corduba (Córdoba), second son of Seneca the Elder, the rhetorician, of Italian or near-Italian stock. Taken to Rome while young and educated by men who combined rhetoric with philosophy, he became famous as a pleader and obtained a quaestorship. The emperor Caligula, jealous of his success, refrained from executing him only because he believed that he was about to die of disease. At the accession of Claudius I (A.D. 41) he was exiled to Corsica through the machinations of Messallina, Claudius' wife, on a charge of adultery with the emperor's niece Julia Livilla, and in spite of lavish imperial flattery was not recalled until A.D. 49; at the request of Agrippina, Claudius' new wife, he was appointed tutor to her son Nero and was immediately made praetor. When Nero became emperor (A.D. 54) Seneca with the collaboration of the praetorian prefect Burrus gradually broke Agrippina's power, turned the maladjusted adolescent emperor to dilettante



BY COURTESY OF THE STAATLICHE MUSEEN, BERLIN

LUCIUS ANNAEUS SENECA, A 3RD CENTURY COPY OF A 1ST CENTURY MARBLE BUST

pursuits and organized efficient government for five years. His power under Nero was based on personal ascendancy, not legal office. In A.D. 59 he was compelled to be privy to Nero's plan to murder his mother and is said to have written the letter to the Senate in which the emperor accused her of conspiracy. Seneca became increasingly irksome to Nero, and the death of Burrus in A.D. 62 finally broke his power. He withdrew from public life and offered to resign the great wealth amassed through political positions, which had brought him discredit; Dio Cassius alleges that his agents practised usury in Britain immediately before the rebellion of Boudicca (Boadicea) in A.D. 60. In A.D. 65 Nero, on detecting the Pisonian conspiracy, had an excuse to be rid of him and ordered his suicide. Seneca met his death unafraid and talked philosophy until the end.

Seneca belonged to the third stage of the Stoic movement, Stoics of imperial times, who placed spiritual counseling higher than first principles (*see* STOICS). His most important philosophical work is the collection of *Epistulae morales* (A.D. 63–65). These letters to Lucilius written in retirement blend Epicurean elements with Stoic exhortation and resignation; they also contain vivid illustrations from personal observation, reflections on literature and satirical presentation of vices similar to those portrayed by his contemporary Petronius. The essay *De clementia* (A.D. 55–56) on the mercy of the just ruler, dedicated to Nero, is a guarded warning against tyranny. His prose works also include the essay *De brevitate vitae*, a masterly analysis of the frivolous occupations of a corrupt society, *De tranquillitate animi*, on participation in public life, three works of consolation addressed to those who had suffered loss, and other moral essays. *Naturales quaestiones* is an exposition of atmospheric and terrestrial phenomena. The so-called correspondence of Seneca with St. Paul is a forgery of the 4th century A.D.

Seneca's prose style, an extreme example of the declamatory rhetorical manner of the 1st century A.D. with its short splintered sentences, epigrammatic concluding phrases (*sententiae*) and wide range of metaphor, was admired in his own day but attacked by Quintilian and other followers of Cicero.

Seneca's *Apocolocyntosis Divi Claudii* ("pumpkinification," a degradation of apotheosis) is one of the masterpieces of Roman satire. It is the only complete surviving example of the Menippean convention (*i.e.*, satire written in a mixture of prose and verse). Composed immediately after the death and deification of Claudius (A.D. 54) it describes the refusal of the gods in their assembly to accept him, and his trial and condemnation in the underworld. Seneca combines savage ridicule of a dead enemy with serious criticism of his political absolutism. The prose parts are urbanely colloquial; the verse insertions include parodies of funeral lament and tragic speech.

Seneca's nine tragedies on mythological themes are different in kind from Greek tragedies, being concerned not with character and motive but with the rhetorical display of intense emotion (*see* LATIN LITERATURE). They were intended for recitation, not for stage production, and in language are influenced by Ovid's elegant artificiality. As speeches, episodes and choruses are independent declamatory entities, the plays lack unity. In *Phaedra* Seneca as Stoic moralist demonstrates the evils of uncontrollable passion, in *Troades* he interprets human suffering and political interrogation in contemporary terms, and in *Thyestes* combines Stoic theory with experience of imperial tyrants. Significant content is, however, frequently vitiated by rhetorical overstatement. The authorship of *Hercules Oetaeus* is problematical. *Octavia praetexta*, a play on a contemporary historical theme, cannot on grounds of subject matter and style be by Seneca, but was probably written by an admirer in the next generation.

Seneca came from a provincial origin to the highest eminence in Rome and was one of the most successfully versatile men in antiquity. It is impossible to resolve the contradictions in his life and work between opportunism and enlightenment, financial unscrupulousness and philosophical resignation. His influence was great: to the Latin Church Fathers he was a salutary castigator of vice and to Renaissance writers a model for drama and a supreme moral teacher.

SENECA (from *Sinnekens*, a Mahican term for Oneida, applied to the upper Iroquois tribes by the Dutch after 1635), a tribe of North American Indians of Iroquoian stock in western New York State. In the 1960s their population exceeded 4,100. To themselves and their confederates they were "great hill people," named for the site of their original village at Canandaigua Lake, where it is said "they sprang out of the ground." As the fifth fire of the Iroquois "Longhouse" (*see* IROQUOIS) they were "keepers of the western door," and the first stop for delegations of "Far Indians" visiting the great council fire at Onondaga (*q.v.*). Their original territory between Seneca Lake and the Genesee River expanded during the 17th century when they destroyed the Neuter and Erie nations to occupy western New York State entirely from Niagara south along the Allegheny River into Pennsylvania. Remote from white contact, secure in game and corn (maize), they could afford to field 1,000 warriors who equaled the combined strength of the rest of the Iroquois League. Never bowing entirely to French or English power, they would remain the League's most important and conservative tribe.

Starting with two prehistoric communities that moved about twice each generation as soil and firewood were exhausted, they expanded into satellite settlements. Throughout history the Seneca have had a leading chief in each moiety (*see* DUAL ORGANIZATION); these offices have descended from the leaders of the two village bands that predate the League. The "Longhouse" was later extended to shelter two more reluctant village chiefs who were made doorkeepers. In New York two great towns (*Kandagaro*, St. Jacques, near Victor; *Sonnontouan* or *Tiotihakton*, Conception, Rochester Junction) and two lesser communities of Huron and Neuter captives (*Gandougarae*, St. Michel, East Bloomfield; and *Gandachiragon*, St. Jean, Lima) persisted during the period of Jesuit missions (1655–87) when J. R. de Brésay, the marquis of Denonville's, expedition destroyed them. For eight years Seneca warriors had composed more than half the war parties that successively destroyed Huron (*q.v.*), Tobacco, Neuter, and Erie nations, making up their own losses by adopting whole towns, until by 1657 they had incorporated 11 different tribes. A century later they were dispersed in 30 villages as far as Ohio. The number of real Seneca dwindled in a population of 5,000 that filled about 300 houses, comprising 900 fireside families of possibly six persons each. These families were linked by maternal kinship as longhouse families and ultimately as eight clans, four in each moiety. One married outside his clan and preferably in the other moiety; both moieties had mainly ceremonial functions in games and funerals.

This social system survived the French and Indian War, Pontiac's conspiracy (*see* PONTIAC), and the American Revolution (in which the Seneca were British allies, resulting in the destruction of their villages by American General John Sullivan [*q.v.*] in 1779). A losing struggle to retain their lands followed the 1784 Treaty of Ft. Stanwix, when their chief Cornplanter (John O'Bail) compromised western Seneca territory. Relief from such humiliation finally came in the treaty of "peace and friendship" signed at Canandaigua (1794), long regarded as basic to land titles and tribal rights. Twelve parcels of land were reserved three years later at Big Tree; four of these reservations (Tonawanda, Cattaraugus, Oil Springs, and Allegany) existed in the 1960s.

At that time chiefs still governed about 700 at Tonawanda, but the Seneca Nation itself was a republic. Councilors were elected by adult males in a population of 3,300 (two-thirds registered at Cattaraugus, and one-third at Allegany, many actually living and

working scattered over the U.S.). In northeastern Oklahoma lived 900 so-called Seneca-Cayuga, descended from the Seneca of Sandusky, Ohio. Though most Seneca were nominally Christian, the followers of Handsome Lake (the Seneca prophet) numbered 800 and maintained the old ceremonies at three longhouses in western New York. The Seneca language was expected to survive for another generation.

Completion of the Kinzua Dam in December 1965, with resulting inundation of Allegany reservation bottomlands along the Allegheny River, forced relocation of the 482 bottomland Seneca. The U.S. appropriated $15,000,000 for this purpose and for rehabilitation, including the building of modern homes for the tribe at Steamburg, N.Y., and elsewhere. *See* also CAYUGA.

SENECIO, the groundsel or ragwort genus of plants, of the composite family (Compositae); one of the most numerous of all flowering-plant genera, it includes about 2,000 species, among them many coarse herbs and shrubs that occur as weeds round the world and several that are cultivated for their flowers, foliage, or climbing growth habit. The leaves are alternate and sometimes all basal. The flower heads are single or clustered, variously coloured, and usually with fertile rays, but sometimes rayless. The surrounding bracts (involucre) are usually arranged in a single series, reinforced at the base with calyxlike shorter bracts (bracteoles). The dry fruits (achenes) are crowned with a pappus of soft, whitish, often very numerous, bristles.

More than 70 species occur in North America, most numerously in the southern and western parts of the United States. Representative American species are the strong-growing *S. aureus* (golden ragwort or swamp squaw-weed), a conspicuous, golden-yellow wild flower, a one- to two-foot-high perennial inhabiting swamps and wet meadows; *S. pseudo-arnica* (seabeach groundsel); *S. obovatus* (round-leaved squaw-weed); *S. pauperculus* (balsam groundsel); and *S. lobatus* (cress-leaved groundsel). Particularly noxious weed species, both in North America and in Europe, are *S. vulgaris* (common ragwort or common groundsel) and *S. jacobaea* (stinking Willie or tansy ragwort), which move readily into fields, pastures, and roadsides. Among the more widely cultivated species are *S. cineraria* (dusty miller); *S. cruentus* (cineraria, *q.v.*); *S. petasitis* (velvet groundsel); and *S. mikanioides* (German ivy), a native of South Africa, naturalized in California.

See also GROUNDSEL.

SENEFELDER, ALOYS (1771–1834), German inventor of lithography, was born at Prague on Nov. 6, 1771, the son of an actor. An author of plays, for the engraving of which he was unable to pay, Senefelder set about engraving them himself. His work on copper plates, however, was not very successful. Further, they were so expensive that he was forced to reuse them, and the necessary grinding and polishing were extremely tedious. His first work on stones began with a fine piece of Kelheim stone he had bought for grinding ink. Since it could be ground and polished easily, he began to use it for practice in writing backward. His discovery of its possibilities for etching came about almost by accident (*see* LITHOGRAPH; LITHOGRAPHY). Senefelder continued his experiments with lithography until the art reached a high degree of excellence. He died at Munich on Feb. 26, 1834, having lived to see his invention brought to comparative perfection.

SENEGAL, REPUBLIC OF (RÉPUBLIQUE DU SÉNÉGAL), since 1960 an independent state, formerly a territory of French West Africa, extends between latitude 12°18′ and 16°41′ N and longitude 11°21′ and 17°32′ E. Area 76,124 sq.mi. (197,161 sq.km.). It is bounded west by the Atlantic Ocean, north by the Senegal River separating it from Mauritania, east by the Falémé River (an affluent of the Senegal) separating it from Mali, and south by Portuguese Guinea and the Republic of Guinea. The state of Gambia forms an enclave in Senegal along the Gambia River, thus isolating the Casamance region, which is the southern part of Senegal. The capital is Dakar.

Physical Geography.—Crystalline bedrock outcrops in the Bondu (Boundou) and Bambouk (respectively in the lower valley of the Falémé and to the west of it, and in the middle valley of the same river and to the east of it) toward the Guinea frontier, where it is surmounted by knolls of Primary sandstones and dolerites of the Fouta Djallon. Most of the country corresponds

MAJOR CITIES AND PHYSICAL FEATURES OF SENEGAL

with the sea gulf of the Cretaceous and early Eocene and consists of sandy clays more or less decomposed into laterite, which gives light soils in all regions. During the Quaternary period, climatic changes brought about the formation of terraces, alluvium estuaries, and Continental and maritime dunes. The sandy clay plains are gently undulating, surmounted by sandstone knolls and dissected by valleys formed by rivers drying up (as in the Sine region between the Dakar Peninsula and the Saloum River) or dried out (as in the Ferlo in the north). The coast, swept by the trade wind and by the prevalent swell from the northwest, is in places bordered by cliffs and by belts of Continental dunes isolating marshy depressions known as *niayes*. Such belts have linked volcanic peaks with the coast to form the peninsula of Cape Verde.

The climate over most of the country is Sudanese (transitional between dry desert and moist tropics); north of a line joining Thiès with the lower Falémé it is Sahelian (peculiar to the edge of the southern Sahara). There are two main seasons: dry and wet, separated by two transition periods. The rainy season lasts from June to October in the Sahelian zone, from May to October in the Sudanese zone, and from May to December in Casamance, with annual rainfalls of about 14 in. (355 mm.) in the north and about 60 in. (1,524 mm.) in the south. It is preceded by a series of tornadoes. Dakar has maximum and minimum average temperatures of 27° and 18° C (81° and 64° F) in January and 33° and 25° (91° and 77°) in August, but the temperature rises rapidly inland, where the trade wind and sea breezes are replaced by the harmattan, a dry warm wind that blows from the east-northeast from January to May.

The vegetation varies with the latitude and climate. In the north the Sahelian zone is characterized by scattered shrubs and spiny acacias and by pasture land of various gramineous plants. South of Cape Verde the savanna grows steadily thicker (African mahogany, silk-cotton trees, palmyras, and baobabs). On the coast are true oases formed by the *niayes* and relict forests of Guinean type, which are also found in Casamance where the tropical forest persists locally. In central and south Senegal the soils are generally leached, by rainfall or because of permeability. Elsewhere ferruginous or sandy belts create infertile soils. In the north the soils are less leached and include fine ferruginous gravels or, in the *tannes* ("marshy depressions"), are saline.

The animal life is Sudanic in type: there are several species of monkey and antelope, warthogs, lions, panthers, hyenas, wild hunting dogs, and hippopotamuses. Most of the large game has been seriously reduced and exists only in the reserves and in the national park of Niokolo-Koba in the neighbourhood of Tambacounda. The numerous birds include partridges, guinea fowl, spur-winged geese, and also the tiny *mangemil*, which does great damage to crops. Among reptiles are crocodiles, turtles and tortoises, monitors, chameleons, huge boas and pythons, and the hooded cobra. Great centipedes, millipedes, scorpions, and numerous kinds of insects are common. (J. D.)

The People.—True Senegalese peoples include the Wolof, Serer, Lébou (Lebu), Fulani (Peul), and Tukulor (Toucouleur). The Wolof, numbering about 1,200,000, inhabit the more populous west. They are very tall, slender, and deep black. They seem to have come from the Sahara and they established formal kingdoms with a well-developed hierarchy. Their society is patrilinear but shows traces of matrilinear origins. They grow millet and peanuts and some are traders. The Serer (*q.v.*), numbering about 500,000, resemble the Wolof but are smaller in stature; they are renowned as farmers. The Lébou (40,000) also resemble the Wolof; they form a group of fishermen in the Dakar region. The Fulani (*q.v.*) number about 400,000. They are light skinned. In the Ferlo they are nomadic herdsmen, but in Casamance they are settled and semiagricultural, and have much intermarried with Negro peoples. The Tukulor (*q.v.*) number about 350,000; they occupy the Senegal River district and have spread southward.

Sudanese peoples in Senegal include about 200,000 Malinke (*see* MANDINGO) in the east, and about 50,000 Sarakolé (Soninke) on the Senegal River around Bakel. These two groups, who cultivate millet, often find work in Dakar and neighbouring towns. The Diola (150,000) of lower Casamance are related to the coastal paleonegritic folk of Portuguese Guinea. They are industrious farmers of the swamps, jealous of their independence and without extensive political organization. The residential Moors, apart from many who come to trade in Senegal, comprise about 20,000, mostly along the river.

The Wolof, Serer, and Lébou languages are distinct but doubtless related. The Fulani and the Tukulor both speak Peul (Poular). The Malinke and Sarakolé speak languages of the Mandingo group; the Diola have separate dialects. French is spoken by the ruling elite, but Wolof is spreading as a commercial language.

The dominant religion is Islam, with a predominance of the Tijaniya (Tidjanist) sect, and around Diourbel, of the Mouride sect. The Diola and a large section of the Serer are pagans, with a few Christians. The houses are generally round, of clay in the east and of straw in the west. The Diola have huge family houses, rectangular in shape and built of clay. They wear few clothes, whereas the other peoples wear ample *boubous* (long robes), with jewels and ornamented leather objects.

Population.—At the 1960 census Senegal had a population of 3,109,840 including 61,700 foreigners (more than half of whom were French). The average density was 40.9 per sq.mi. (15.8 per sq.km.) but distribution varied considerably, being 10 or below in the river area, about 1 in the Ferlo, reaching 50 in the hinterland of Dakar and Thiès, 400 in the Cape Verde Peninsula, about 2 in the east, and between 5 and 15 in Casamance.

Apart from Dakar (*q.v.;* pop. [1958] 194,605, commune) the chief towns are Rufisque (47,000, commune), Thiès (36,246, commune), and Saint-Louis (*q.v.*), the former capital with 37,104 inhabitants. Kaolack (*q.v.*) is the port of the Saloum River and Ziguinchor (28,483) is the chief town in Casamance.

History.—Man has occupied Senegal since very ancient times. Paleolithic axes, Neolithic two-headed axes and arrows have been found near Dakar, and stone erections as well as copper and iron objects in the Sine-Saloum region.

The first Negroes of whom there is historical mention are the Tukulor, who occupied the Senegal Valley in the 11th century. The name Senegal appears to be derived from that of the Zenaga Berbers of Mauritania. The Sarakolé empire of Ghana lay to the east, between the Senegal and the Niger. Toward 1040 the Zenaga established, perhaps on an island of the river, the Muslim monastery in which the Murabti sect was to have its origin. This sect converted the Tukulor, destroyed Ghana, and conquered Morocco. Pagan invasions began in the 13th century. About 1400 some Fulani founded a dynasty on the middle Senegal, in the region thereafter known as Fouta-Toro. In the 18th century the Muslim Tukulor revolted and set up a feudal theocratic republic.

On the coast and in the Cayor the Wolof founded an independent kingdom; this was later divided into four states: Dyolof, Walo, Cayor, and Baol, which were often at war with each other and with their neighbours. As well as the warrior aristocracy, the Muslim marabouts also had some influence there. The Serers in the Sine and in the Saloum were organized into states by Mandingo chiefs, the Guellawar. The other peoples did not form any large states.

Portuguese navigators reached Cape Verde about 1444. They set up factories at the mouth of the Senegal, at Gorée (opposite the modern Dakar), at Rufisque (Rio Fresco), at Joal, at Portudal, in the Saloum, and in Casamance (Casa Mansa).

In 1638 a French factory was set up at the mouth of the Senegal and was rebuilt, in 1659, on N'Dar, an island in the river, which was to become Saint-Louis du Sénégal. The Dutch meanwhile had set themselves up on the island of Gorée (*q.v.*), which the French took over in 1677, after which the French agent J. B. Ducasse managed factories on the coast and did much to promote trade. Dealers from Saint-Louis began business on the lower reaches of the river, where they bought gums and slaves. André Brue spent 25 years trying to penetrate the hinterland by journeys up the Senegal. In 1700 he built Fort Saint-Joseph near the Falémé confluence and began to buy gold from the Bambouk. After his death this fort was destroyed by the Negroes. The French botanist Michel Adanson (1727–1806) spent five years exploring the interior before publishing his *Histoire naturelle du Sénégal* (1757).

The English occupied the factories during the Seven Years' War, and gave only Gorée back at the conclusion of peace in 1763. The duc de Lauzun recovered Saint-Louis in 1779; one of its first governors was the chevalier de Boufflers (1738–1815), whose love letters to Mme de Sabran contained descriptions of the country. François Blanchot de Verly, who became governor in 1787, had to endure a blockade and great privations but nevertheless was able to repel several English assaults. He died in 1807, and Saint-Louis surrendered two years later. The English governor had a mausoleum built for the gallant Blanchot.

In 1816 Saint-Louis and Gorée were returned to France. In the same year, on an expedition to Senegal, "La Méduse" was shipwrecked; this incident gave rise to Géricault's famous painting "Raft of the Medusa." Julien Schmaltz, as governor, founded a station up the river at Bakel. Schmaltz also tried to grow cotton in the neighbourhood of Saint-Louis, and his successor Baron Roger continued this experiment, but it came to nothing; after which trade was confined to gum. In 1818 Gaspard Mollien crossed the Ferlo and reached the Fouta Djallon, discovering the sources of the Senegal and Gambia rivers. Between 1835 and 1837 two stations, Carabane and Sedhiou, were acquired in Casamance.

The precarious position of the French, local wars, and the tribute paid to the Negro kinglets, all combined to reduce trade to very little. Under the Second Republic the slaves were emancipated and given French citizenship. In 1854, at the request of the businessmen of Saint-Louis, Comdt. Louis Léon César Faidherbe (*q.v.*) was appointed governor. To put an end to insecurity Faidherbe pacified the Walo east of Saint-Louis and then drove back the Moors on the right bank of the river. But the Tukulor marabout Omar el-Hadj was threatening the river. Faidherbe established a station at Médine (near Kayes) and left there a small garrison under Paul Holle, a mulatto from Saint-Louis. In 1857 Holle strenuously resisted attacks of the marabout's thousands until the rising of the high water enabled Faidherbe to reach him with reinforcements. In 1857 Captain Protet, of the French Navy, founded a station at Dakar. Faidherbe occupied the Cayor, thus uniting parts of the colony. In 1865 he went back to France, having organized Senegal and laid the foundations of native policy based on respect for existing usages.

His successor, Col. J. M. E. Pinet-Laprade, consolidated his work, occupying the Petite Côte and the Saloum and developing the town of Dakar. Peanuts had been introduced into the Cayor and were being exported from Rufisque. The Gambian fort of Albreda had been ceded to Great Britain in 1857. In 1886 the last Wolof king, the damel of Cayor, Lat Dior, had been killed during an insurrection, and Col. J. S. Galliéni was destroying the power of the marabout Mamadou Lamine in the east. Faidherbe's creation of the Tirailleurs Sénégalais (Senegalese riflemen) marks the beginning of France's use of Senegal as a base for expansion into the Sudan and toward the Rivières du Sud. Dahomey was conquered (1892–94) by Col. (later Gen.) Alfred Amédée Dodds (*q.v.*), another mulatto soldier from Saint-Louis who had subdued the Dyolof and the territory of the Tukulor. The pacification of the traditionally anarchic Lower Casamance was not achieved until 1903. The Gouvernement Général de l'Afrique Occidentale, established by decrees of 1895 and 1904, was at first the responsibility of the governor of Senegal, resident at Saint-Louis, but was later raised to the status of a separate authority based on Dakar. The latter town grew rapidly, to become the main port for Senegal and for the French Sudan.

In World War I the Negro deputy for Senegal, Blaise Diagne, helped to enlist large numbers of riflemen. In World War II the governor-general, Pierre François Boisson, remaining loyal to the Vichy government, held Dakar against a British attack in 1940; but he transferred his allegiance to the Allied side in November 1942. In 1946 all Senegalese became French citizens, whereas previously this right had been restricted to natives of the four ancient *communes*, Saint-Louis, Gorée, Dakar, and Rufisque; and the colony became an overseas territory of France. The two Senegalese deputies, Lamine Gueye and Léopold Sédar Senghor, played a prominent role in the drawing up of the French Constitution of 1958. In 1958 Senegal became an autonomous republic within the French Community; in September 1960, after a short period of federation with the Sudanese Republic in the Mali federation, Senegal was recognized as an independent state, remaining within the French Community. Senghor was elected president of the Republic. In December 1962 a tentative *coup d'état* by the president of the Council of Ministers, Mamadou Dia, failed and Senghor took over the office. (HU. DE.)

Administration and Social Conditions.—Under the 1963 constitution Senegal is a presidential republic, in which a National Assembly of 80 members elected by universal suffrage exercises legislative power. The assembly, together with the delegates of the provincial and communal councils, elects the president. The president appoints the prime minister. The ministry is responsible to the assembly.

Administratively the republic is divided into seven regions (Kaolack, Sine-Saloum, Thiès, Fleuve, Sénégal Orientale, Cap-Vert, and Casamance), each with a governor and local assembly and each subdivided into *départements*.

Elementary and secondary education are provided by schools and colleges, some of which are conducted by missionary bodies, with an increasing enrollment. Further education is provided by *lycées* at Dakar and Saint-Louis, technical and training colleges, and by the University of Dakar established in 1957.

Economy.—The traditional agricultural economy varies in the different regions. Cattle raising is practised by the Fulani in Bondu, and also in the Ferlo where a scattered bushy vegetation allows widespread seasonal migration of stock. Agricultural techniques vary; thus the soils along the Senegal River are cultivated by using the floodplain after the waters have subsided; by building dikes; or by dry farming. Millet cultivation is associated with cattle raising. The savanna regions are cultivated by the slash and burn method and with long fallow periods, although the Serer practise crop rotation (millet, peanuts, fallow). Irrigated cultivation is used in the *tannes* of the Sine district and in Casamance by the Diola, who have managed to polder the estuarine mud by arrangements of canals, sluices, and dikes. Fishing is carried on by the Lébou of the Cape Verde Peninsula and by the Guet N'Dar fishermen at Saint-Louis, and also in the rivers.

The economy introduced by Europeans is one of the oldest in Africa. Trade, initially concerned with slaves, developed chiefly in gum and peanuts. The soil, the population density, and the existence of maritime outlets encouraged peanut cultivation to an extent that transformed the country. First practised in the north, peanut cultivation spread along the routes of communication and toward the wetter south, to such an extent that labourers (*navétanes*) had to be brought from neighbouring countries. At one time, indeed, the cultivation of staple foodstuffs was neglected, the vegetation stripped, and the soil exhausted. But the use of mineral fertilizers and the distribution of selected seed and of agricultural implements resulted in increased yields, especially after World War II. By the mid-1960s annual harvests averaged 900,000 metric tons. Traditional methods have been improved by horse-drawn plows, and the establishment of regional (cooperative) development centres and some mechanized agricultural experiments. Harvesting activity reaches a peak from November onward.

The risks inherent in a single-crop economy and the growing needs of the population compelled the authorities to develop other food crops and to utilize new acreage. Work was undertaken to drain the *tannes* of the Saloum River and to increase the productivity of the Senegal Valley. Also, the cultivation of rice in the Senegal Delta was extended by pumping water from a dam on the Tauey effluent of Lake Guiers. Increased peanut production and the development of the port of Dakar (*q.v.*) encouraged small consumer and construction industries in that city and its environs. But lack of mineral resources precludes the development of heavy industries; the only minerals extracted are salt (Kaolack), ilmenite, and zircon near the coast (Rufisque) and phosphates of lime and of alumina near Thiès.

A four-year development plan (1961–64) was launched to encourage capital investment, especially in industrial development.

The chief imports of Senegal are wheat, rice, sugar, petroleum products, textiles, and machinery. The chief exports are peanuts, peanut oil, oilcake, phosphates, and titanium concentrates. Chief trading partners are France and countries of the franc zone, and the Federal Republic of Germany. As a member of the Association of African States, Senegal signed a convention of association with the European Economic Community in July 1963. Senegal is also a member of the West African Monetary Union (established in May 1962). Its currency is based on the franc CFA (1 fr. CFA = 0.02 French francs).

Communications.—Initially, links with the interior were maintained by the Senegal River, along which ports of call were established and on the estuary of which lies Saint-Louis. But the river is navigable only during the summer flood season, when there is little to transport. Therefore between 1880 and 1923 the metre-gauge Dakar-Niger Railway was built in stages, and extended in 1922–31 by branch lines to Kaolack, Linguère, and Touba. This redirected the flow of trade to Dakar, which has a well-equipped port and an airport used by international and local services. But the river ports of Kaolack and Ziguinchor were little developed. Road links between Dakar and the countries adjoining Senegal were completed after World War II. Radio diffusion du Sénégal, in Dakar, broadcasts in French and a number of vernacular languages and the Dakar area has a television service.

SENEGAL RIVER in West Africa flows into the Atlantic Ocean. It is 1,015 mi. (1,633 km.) long and is formed by the union of three rivers of which the Bafing (Black River) and the Bakoy (White River) rise in the Fouta Djallon Plateau and drain north, joining at Bafoulabé; tributary to the Bakoy is the Baoulé. The principal tributary, the Bafing, flows north from the southern slopes of the Fouta Djallon in a generally enclosed valley,

its course including a series of rapids and falls, notably the Gouina and Félou. Below Kayes, 559 mi. (900 km.) from its mouth and only 197 ft. (60 m.) above sea level, the river (known as the Senegal below Bafoulabé) flows through a wide valley named Fouta Toro between Bakel and Dagana. It forms the frontier between the republics of Mauritania and Senegal; the right-bank flood plain in Mauritania is known as Chemama. The only major left-bank tributary is the Falémé; right-bank tributaries are of no significance in this part of its course as the valleys of Mauritania are dry most of the year. At low water the river flows in *marigots* (lateral channels) between islands of sand, *e.g.*, Île à Morphil, and alluvial banks which isolate the main river bed from the flood plain. Downstream from Kaédi the river passes through a region of northeast-southwest trending dunes. Below Dagana lies the delta with its many distributaries; the Senegal estuary is blocked by a sandbar and a 15-mi.-long sandspit, Langue de Barbarie. Near the head of the delta two minor tributaries of the Senegal drain the lakes Rkiz (Cayar) to the north and Guiers to the south.

The headstreams of the Senegal drain the well-watered plateau region where annual rainfall varies between 40 and 80 in. (1,000–2,000 mm.), but below Bakel rainfall is less than 20 in. (500 mm.). Percolation and evaporation contribute in reducing the total discharge of the river. The regime is seasonal; summer floods begin upstream in July but are not felt at Dagana until the end of August. The floods vary considerably in volume; in September they usually exceed 105,900 cu.ft. (3,000 cu.m.) per sec. but many reach as much as 247,200 cu.ft. (7,000 cu.m.) per sec. at Bakel, and the water there rises 30 ft. (9 m.) above low-water mark. The river is navigable throughout the year as far as Podor but during the floods (for 2½ months) Kayes can be reached. Because of the sand obstructions at the mouth and its seasonal nature the river is little used for transport except by local craft. Water level drops considerably during the dry season; the rate of flow at Bakel drops to 106 cu.ft. (3 cu.m.) per sec. at the close of the dry season. At these times the tide is felt above Dagana and sometimes above Podor.

In 1947 under the direction of the *Mission d'Aménagement du Sénégal* (MAS) a scheme to irrigate the flat land to the southwest of Richard Toll was begun. A barrage on the Taouey River prevents salt water from penetrating Lake Guiers in the dry season. Further work has been undertaken to make the valley more productive, and a project was prepared to use the falls of Félou and Gouina to regulate the water level and produce energy. (J. D.)

SENESCHAL (Lat. *senescalcus*, from Old Teutonic *seni*, "old," *skalko*, "servant," the oldest and thus the senior servant) was, from Merovingian times, the official who had charge, under the major domus or mayor of the palace, of the personnel of the royal household. Under the Carolingians he became responsible for organizing the journeys of king or emperor, and by 1071 was steward of the household, head of the army, and administrator of the royal demesne. With the title *dapifer* he headed the names of those witnessing royal diplomas. In 1107 the office passed from the powerful family of Rochefort to that of Garlande. But Étienne Garlande, already chancellor when he became seneschal in 1120, was deprived in 1127, and Louis VI gave the office (1131–52) to his own cousin Raoul de Vermandois. When Thibaut V, count of Blois, was seneschal (1152–91) the office seems to have been only honorary, and on his death no new seneschal was appointed.

Most of the great French feudatories, the dukes of Normandy and Aquitaine, the counts of Anjou, Poitiers, and Toulouse, had their seneschals. In Anjou and Poitou the title was given to subordinate officials on the counts' demesne. When these provinces became united to the crown after 1203, these officials were retained to perform the same duties as the bailiffs of the royal demesne elsewhere. This was the basis of the later classic administrative division of France into *bailliages* and *sénéchaussées*, although in Normandy, Maine, Anjou, and Auvergne the seneschals were replaced by bailiffs.

SENIGALLIA (SINIGAGLIA; anc. SENA GALLICA), a seaside resort and episcopal see of the Marches, central Italy, in Ancona Province, lies on the Adriatic coast, 17 mi. (27 km.) NW of Ancona town. Pop. (1961) 34,884 (commune). Principal buildings include the castle (1480); the Convento Delle Grazie (15th century) with a Madonna by Perugino; the 17th-century Palazzo Comunale and the Chiesa della Croce with a Deposition by Barocci; and Portici Ercolani (18th century). The town is a market centre of a predominantly agricultural area, and manufactures cement, bricks, agricultural implements, paper bags, and furniture. It is on the Adriatic state road and on the Bologna-Bari railway, and is served by the airfield at Falconara, 11 mi. (16 km.) SE. It has a small port. Sena Gallica was founded by the Senonian Gauls in the 6th century B.C., and became a Roman colony *c.* 290 B.C. In the 6th century A.D. it was one of the five cities of the Pentapolis. It was destroyed by the Arabs in 1264 and rebuilt by Sigismondo Malatesta of Rimini in 1450. Its lordship was assigned to the Della Rovere family by Pope Sixtus IV (late 15th century). It became part of the papal states from 1631 to 1860, and in this period was famous for its fair. Pope Pius IX was born at Senigallia in 1792. (R. CI.)

SENLIS, a small town of northern France, headquarters of an *arrondissement* in the *département* of Oise, 27 mi. (43 km.) NNE of Paris by road. Pop. (1962) 8,717. It is situated on the right bank of the Nonette River, a tributary of the Oise, among the extensive forests that occupy the sand cappings overlying the Tertiary limestone of the Île-de-France. Senlis was part of the royal domain and a royal residence from the time of Clovis (d. 511), and Hugh Capet was proclaimed king there in 987. The town has an inner perimeter of massive Gallo-Roman walls; and the remains of an outer ring of medieval walling. Senlis is rich in medieval buildings, including the ruins of the royal castle and the former cathedral church of Notre Dame, one of the finest achievements of Gothic architecture, which was begun on a grand scale in 1155, but not completed until the 16th century. Senlis is now a much frequented, convenient resort for Parisians. (AR. E. S.)

SENNA, a popular purgative, consisting of the leaves of *Cassia acutifolia* or *C. angustifolia*, plants of the pea family, Leguminosae. These are small shrubs about 2 ft. high, with numerous lanceolate leaflets arranged pinnately on a main stalk with no terminal leaflet; the yellow flowers are borne in long-stalked racemes in the leaf axils and are succeeded by broad flattish pods about 2 in. long. *C. acutifolia*, native to tropical Africa, is the Alexandria senna of commerce. *C. angustifolia* is the Bombay, East Indian Arabian, or Mecca senna of commerce. This plant grows wild in Arabia, Somaliland, Pakistan, and the Punjab, India. It is also cultivated in the extreme south of India, and there grows larger leaves, known commercially as Tinnevelly senna.

The laxative principles are apparently two glycosides, sennoside A and sennoside B, and the anthraquinone, emodin. Senna was introduced by the Arabs, who described its cathartic properties as early as the 9th century.

SENNACHERIB (Akkadian SIN-AKHKHE-ERIBA) (d. 681 B.C.), king of Assyria from 705 to 681 B.C., was the son and successor of Sargon II (*q.v.*). His most enduring work was the rebuilding of Nineveh and its adoption as the capital, which it remained until the fall of the Assyrian Empire. He carried out a great scheme of town planning, laying out streets, widening the squares, and providing the palace area with a wall of limestone slabs for flood protection. The palace itself, with paneling and doors of aromatic woods, was of great splendour, showing some features of Syrian construction. By the palace a botanical garden and orchards were laid out, a canal being cut for six miles to bring water to them. Sennacherib expressly mentions that this splendour was created through the slave labour of conquered peoples. (*See* further NINEVEH.) This king was keenly interested in technology, and he mentions a new method of metal casting devised in his reign and the discovery of new mineral resources.

The peace bequeathed by Sargon was broken after two years by the insurrection in Babylonia of Merodach-baladan, who had

united the Chaldean and Aramaean tribes behind him, secured the support of Elam, and worked for a widespread anti-Assyrian coalition involving, among others, Hezekiah of Judah (Isa. 39:1; II Kings 20:12). Merodach-baladan occupied Babylon and held other cities in northern Babylonia with Elamite troops. By clever generalship Sennacherib cut Elamite communications, whereupon northern Babylonia fell into Assyrian hands, Babylon receiving Sennacherib with enthusiasm (703 B.C.). The Assyrian army then occupied and defortified the Chaldean area in south Babylonia, which was left under Assyrian officials, a native Babylonian, Bel-ibni, being made king in north Babylonia. A rebellion broke out in 701 B.C. in Palestine, Hezekiah of Judah, in alliance with Egypt, being involved (*see* HEZEKIAH). A strong Assyrian force overran Palestine, defeated the Egyptian troops and took the rebel cities, with the exception of Jerusalem, which was spared on payment of a heavy indemnity (*cf.* II Kings 18–19; it was 19:35 that inspired Byron's well-known poem, "The Destruction of Sennacherib").

Meanwhile Merodach-baladan began fresh intrigues in Babylonia, so that in 700 B.C. another Assyrian foray into Chaldean territory was necessary. Bel-ibni, who had proved unable to maintain order, was replaced by Ashur-nadin-shum, a younger son of Sennacherib, who reigned for six years. Merodach-baladan died shortly after, but his Elamite allies, in whose territory disaffected Chaldean tribesmen were able to find sanctuary, remained a threat to Babylonian security. Sennacherib sent a fleet of ships down the Euphrates and attacked Elam by sea across the Persian Gulf (694 B.C.), looting the Elamite cities and taking prisoner survivors of Merodach-baladan's tribe. With the Assyrian forces still in the south, Elam reacted by a raid into metropolitan Babylonia, capturing Ashur-nadin-shum and replacing him with a Babylonian puppet. The returning Assyrian army dealt with the Elamite nominee, but a new Chaldean leader, Mushezib-Marduk, had emerged and held Babylon. After the Assyrian army had returned home, Mushezib-Marduk offered a considerable bribe and obtained massive military support from Elam. The Elamite and Assyrian armies met at the Diyala and a bloody carnage ensued, leaving the Assyrian army incapable of following up immediately the victory it claimed. In the following year, 689, the Assyrians were able to deal with Mushezib-Marduk, whose forces, after a nine months' siege in Babylon, were finally defeated. Sennacherib, departing from previous Assyrian policy, savagely looted and sacked Babylon.

Sennacherib died at Nineveh in January 681 at the hands of his sons. *See* also BABYLONIA AND ASSYRIA.

SENNAR, a town in the Republic of the Sudan and the name of the area between Nubia (*q.v.*) and Ethiopia (Abyssinia). The town lies at the western end of the Sennar Dam on the Blue Nile, 110 mi. (177 km.) S of Khartoum. Pop. (1955–56) 8,093. Sennar as the name of the area was not known before the 16th century. It derived from Sennar, the capital of the Fung (Funj) kingdom, a Muslim dynasty known as the Black Sultanate (*sultana zerqa*), which with an 'Abdallab Arab viceroy ruled (1504–1821) most of what is now the Republic of the Sudan. The old capital town of Sennar, now uninhabited, was situated on the west bank of the Blue Nile a mile or so downstream of the site of the Sennar Dam and near Sennar railway junction, from where lines run west to El Obeid and Nyala, north to Khartoum, east to Kassala, and south to Ar Rusayris (Er Roseires).

The Sennar Dam, 9,922 ft. (3,025 m.) long with a maximum height of 130 ft. (40 m.), was completed in 1925 and irrigates the cotton and other crops in the Gezira (*q.v.*). It is sited on a rocky sill which provided a ford across the Blue Nile in Napatan and Meroitic times, and remains of both these periods have been found there. The ford was also presumably the reason for the siting of the Fung capital on an important route between the kingdoms of Darfur and Abyssinia.

The Fung kingdom replaced the southern Christian kingdom of 'Alwa, which had gradually collapsed after the Muslim conquest of the Christian kingdom of Mukurra (Dongola) in the 14th century. Who the Fung were is not yet certain, but it is believed that the ruling family were a cadet branch of the Muslim Bulala royal family of Bornu, who were expelled *c.* 1500 after a civil war and who, on arrival on the Nile, defeated the Arabs under the 'Abdallab at Arbagi. The name Fung is probably a corruption of the Shilluk word for strangers which was given to them on their arrival on the White Nile, and the name Hameg (Hamaj), which they gave to their indigenous subjects, came with them from Lake Chad, where it is used for the subject population. The Fung Chronicle, composed *c.* 1800, gives the names of the sultans and details of the later history. An indeterminate war was fought with Abyssinia (1618–19). In 1704, Jacques Le Noir du Roule, a French envoy to Abyssinia, was murdered at Sennar, and in 1744 an Abyssinian attack on Sennar was defeated (largely by the strategy of an exiled Darfur prince). In 1821 the degenerate Fung kingdom surrendered to Ismail Pasha without a struggle. Sennar then became the capital of a Turko-Egyptian province of the same name, until it was destroyed by the Mahdists after a siege in 1883. For some time it was the headquarters of a province under the Anglo-Egyptian condominium but was later reduced to a district. *See* also SUDAN, REPUBLIC OF THE: *History*.

See A. J. Arkell, *History of the Sudan* (1961). (A. J. AL.)

SENNETT, MACK (MICHAEL SINNOTT) (1880–1960), creator of the Keystone Kops and father of American slapstick comedy, was a dominant figure in the early era of U.S. film production. He was born at Richmond, Que., Jan. 17, 1880. Joining Biograph studios in 1909 after unsuccessful sorties into circuses and burlesque, he learned movie technique from D. W. Griffith (*q.v.*), then left to form his own independent Keystone Company late in 1911. At first he both directed and acted in his short comedies, many of which were improvised on the spot to take advantage of parades, fires, and similar events too costly to stage. Although his name is generally associated with bathing beauties and custard pies, the vintage Sennett films (1914–24) were often biting parodies or incisive satires that mocked the foibles of an increasingly mechanized society. He developed a coterie of clowns and comediennes that made the Keystone trademark world famous —Mabel Normand, Marie Dressler, Gloria Swanson, Roscoe ("Fatty") Arbuckle, Harry Langdon, Ben Turpin, and Charlie Chaplin among them. In 1914 Sennett's company produced the first American feature-length comedy, *Tillie's Punctured Romance*, and in 22 years he turned out more than 1,000 short subjects. The coming of sound and the advent of double features, combined with the Wall Street crash that wiped out his large personal fortune, severely crippled Sennett's style, and he retired in 1933. In 1937 the Academy of Motion Picture Arts and Sciences voted him a special award "for his lasting contribution to the comedy technique of the screen." He died in Hollywood on Nov. 5, 1960.

See Gene Fowler, *Father Goose* (1934); Mack Sennett, as told to Cameron Shipp, *King of Comedy* (1954). (A. KT.)

SENOI, a Veddoid people (*see* VEDDA) found in the Malay Peninsula and in small groups along the coastal plains of Siak in Sumatra. In the 1960s they were estimated to number between 20,000 and 27,000. Traces of such a people also appear in the eastern islands of Indonesia. Apparently they are remnants of a once widespread population that followed the Negrito into this area. They are sometimes known as Sakai, a derogatory term applied by the Malays. In the peninsula they speak a language apparently related to or influenced by Mon-Khmer, but in Sumatra they have adopted the language and matrilineal institutions of the Menangkabau (*q.v.*). There are indications that the Senoi entered the area with a well-developed dry land agriculture; and that they lived in communal houses and had some degree of political development. Despite their cultivation of manioc and rice, they are also active in hunting, fishing, and food gathering. In the hunt they employ the blowgun and poison darts, like the neighbouring Malay and Negrito (*see* SEMANG) of the peninsula. Their highly developed religious beliefs and practices stand in sharp contrast to their rather primitive material culture. Where there has been little intermixture the Senoi differ markedly from their neighbours. They are slight in build, short in stature, with long heads, and generally have lighter skin colour and narrower noses than the Malay or Negrito (*qq.v.*). Their long hair is allowed to grow until

it falls in curls over their shoulders. Although skilled in basketry, they do not weave or do metalwork. *See* also MALAYSIA; MALAY ARCHIPELAGO: *Anthropology*.

SENONES, the name of two ancient Celtic tribes, or perhaps rather of two divisions of the same people, one living in Gaul, the other in Italy. The Gallic Senones lived in the area which includes the modern French *départements* of Seine-et-Marne, Loiret, and Yonne. They fought against Caesar (53–51 B.C.); in 51 a Senonian named Drappes threatened the province of Gallia Narbonensis, but was captured and starved himself to death. In later times they were included in Gallia Lugdunensis. Their chief town was Agedincum (later Senonus, whence Sens). The Senones in Italy crossed the Alps into Italy, perhaps *c.* 400 B.C., and settled on the east coast between Ariminum (Rimini) and Ancona, in the so-called *ager Gallicus*, driving out the Umbrians there. In 391 they invaded Etruria and besieged Clusium. Roman intervention, in reply to an appeal from Clusium, led to the Gallic capture of Rome (390). Livy and Diodorus, but not Polybius, record that the Senones led the Gauls that captured Rome. For the next century the Senones were hostile to Rome, but they were finally defeated and expelled by P. Cornelius Dolabella in 283. Their territory was used either for colonies—Sena (Senigallia) and Ariminum—or for the allotments for individual Roman citizens that were proposed by Flaminius in 232 B.C.

SENS, a town of north-central France, centre of an *arrondissement* in the *département* of Yonne, Burgundy region, and an archiepiscopal see, lies on both banks of, and on an island in, the River Yonne, 70 mi. (113 km.) SE of Paris by rail. Pop. (1962) 19,692. The central part of the town is on the right bank of the river, and is enclosed by broad, wooded boulevards on the site of the old Roman fortifications, of which there are some remains. The chief monument is the Cathedral of Saint-Étienne (*c.* 1130–16th century), one of the earliest examples of the Gothic style. The architect of its nave and choir (completed *c.* 1168) was William of Sens, who later rebuilt the choir of Canterbury Cathedral. The west front has three portals with 12th-13th-century carvings, those above the central portal depicting the life of St. Stephen (Étienne). Only the southern tower was ever completed; it was reconstructed during the 14th-16th centuries. The cathedral has magnificent stained glass of the 12th–17th centuries, and its treasury, one of the richest in France, contains a collection of ancient fabrics and liturgical vestments, including those of St. Thomas Becket. It was in the cathedral of Sens that St. Louis, in 1234, married Marguerite of Provence. South of the cathedral are the 13th-century officiality (now a lapidarium), restored in 1849 by Viollet-le-Duc, and the mainly 16th-century archbishop's palace. The earliest sanctuary of Sens is the partly Romanesque Basilica of Saint-Savinien, the foundation of which dates from the 3rd century. The municipal museum and library have an important collection of Gallo-Roman sculpture, a 5th-century ivory diptych, and some precious manuscripts. There are several 16th-century houses, including the Jean Cousin museum of local history and the so-called "House of Abraham."

Sens is on the Paris-Lyons-Mediterranean railway and is also connected by bus with Montargis and Troyes. It is intersected by the Paris-Geneva and Nancy-Orléans trunk roads. The navigable Yonne links it to the French inland waterways system. Important industries are tanning, flour milling, metalworking, and the manufacture of dairy products, cutlery, electric cables, chemicals, brushes, and articles of plastic, horn, and whalebone. An agricultural and commercial fair is held annually.

Sens (Agedincum) was the capital of the Senones, a powerful Gallic tribe. The Romans first subdued it after the defeat of Vercingetorix. In 395 it became the metropolis of the 4th Lugdunensis, whose boundaries became those of the archiepiscopal see. The inhabitants, converted by the martyrs Savinien and Potentian repelled the Alamanni and the Franks in 356, the Saracens in 731 or 738, and the Normans in 886. Several ecclesiastical councils were held in Sens, notably that of 1140, at which St. Bernard and Abelard met. Granted a communal charter in 1146, it suffered in the Hundred Years' War, was an early member of the Holy League, and was deprived of its privileges by Henry IV. The archbishopric, dismembered in 1622 on the elevation of Paris (hitherto suffragan to Sens), was reduced to a bishopric in 1791. This was suppressed during 1801–17, but in 1817 the archiepiscopal see was restored.

SENSATION commonly denotes any concrete conscious experience resulting from stimulation of a specific sense organ, sensory nerve, or sensory area in the brain. The word is used in a more general sense to indicate the whole class of such experiences. In ordinary speech the word is apt to be ambiguous; it is frequently used so as to leave uncertain whether the speaker is referring to the process of sensing, or to whatever it is that is thereby sensed (the apparent painful stimulus, sound of a bell, or red glow of a fire). This double meaning has produced confusion about whether or not sensations are purely mental (as opposed to physical). Though the process of sensing is thought by some to be purely mental, some psychologists and philosophers hold that what is sensed is normally a physical quality existing independently of mind; *e.g.*, the grass is literally green whether or not any person is present to perceive it (*see* REALISM). To avoid this ambiguity Bertrand Russell introduced the term sense-datum to signify what is sensed or "given in sensation," and later writers proposed the term sensum; the word sensation is then reserved for a so-called mental process or activity (*see* KNOWLEDGE, THEORY OF: *Epistemology in the 20th Century*).

More empirically inclined psychologists and physiologists prefer to regard sensation as a concept (not a datum) defined in terms of dependent relationships between discriminatory responses of organisms and properties of physical stimuli. Characteristics of sensory functions may be ascertained by training a laboratory animal or asking a human being to respond differentially to various aspects of the stimulus. This approach regards sensation much as sensing is regarded in modern automated devices (*see* AUTOMATION: *Elements in an Automated System*). Sensing elements (sensors) in automated systems indicate characteristics (presence, absence, intensity or degree) of some form of energy impinging on them. These sensors are called transducers; they convert their input energy into electrical currents that can be used as signals. For example, the electrical current generated by a photocell can be used as a signal indicating the intensity of a light falling on the photocell (*e.g., see* SELENIUM CELL). When the signal reaches a critical strength, a relay may be activated to start a motor. The motor starts (responds) when the photocell senses light of a certain intensity. The definition of sensation in terms of discriminative responses in living organisms is analogous. When a stimulus impinges on a sense organ and the organism responds appropriately it is said that the stimulus has been sensed. Nonetheless many people (including some psychologists) regard a mentalistic definition of sensation as basic to the psychology of sensation. Historically, conceptual formulations regarding sensation arose out of mentalistic philosophies (*see* IDEALISM) that deny efforts to equate the terms mental and physical (*see* MATERIALISM; FECHNER, GUSTAV THEODOR; EPIPHENOMENALISM).

Toward the close of the 18th century, Thomas Reid (*q.v.*) argued that, although sensation furnishes purely mental experiences (*e.g.*, those called pain, colour, sound and smell), perception yields direct awareness of physical things that exist independently of a percipient (*see* PERCEPTION). The associationists, however, held that objective reference and meaning are given to a sensation by the addition to it of other sensations or images (memories of sensations), as when the smell of a rose is identified by the associated visual image of a rose (*see* ASSOCIATION, MENTAL). Indeed this was the commonly accepted doctrine of the 19th century: perception is more complex than sensation, involving both sensations and images; perception refers, as sensation does not, to

an object and may also have other meaningful implications; and the complexity of perception adds meaningful reference to it.

But toward the close of the 19th century critics of the associationistic school strongly denied that percepts are compounded by adding mental images to actual sensations. They held that objective reference is present in every form of sensory awareness from the very first, and that the percept is a synthetic unity given directly in ordinary experience. When a child first sees a jumping, barking dog and screams with fear, he does not begin by noticing a brown sensory patch moving about, then connect it with noise, and finally associate both with the mental image of a possible bite to perceive a complex object in the external world. His cognitive response was held to be the immediate result of built-in mechanisms through which he at once perceives a dangerous-looking animal.

In the 1960s the differentiation of perception from sensation was of little systematic or theoretical significance in objective psychophysiology. While discrimination of fundamental stimulus dimensions (*e.g.*, wavelength or intensity of light) may be said to indicate sensation, and discrimination of more complex stimulus patterns (*e.g.*, speech sounds, visual space or shape) can be said to involve perception, the distinction is historical and conventional, and the terms are often interchanged.

Senses.—Traditionally, there are five classical senses (*see* HEARING; SMELL AND TASTE; TOUCH; VISION). This simple classification is helpful as far as it goes, but touch, for example, is known not to be a simple unitary modality; even as commonly used, the word includes cutaneous sensations of heat, cold, pain, and pressure. Thus, throughout the body are free nerve endings that uniquely mediate sensations of pain. The traditional list must also be expanded to include organic sensations sometimes grouped under the term somesthesia, and subdivided as kinesthetic, vestibular (static), and visceral. Kinesthesia, so named because it mediates awareness of bodily movement, posture, and perception of weight, arises from sense organs in muscles, tendons, and joints; it furnishes sensory clues that permit precise movements. The vestibular sense mediates balance, bodily posture, and sensations of rotation and dizziness; its sense organs are part of the inner ear (*see* EAR, ANATOMY OF; EQUILIBRIUM, ANIMAL; VERTIGO AND DIZZINESS). The kinesthetic and vestibular senses are often classified as proprioceptive; they are stimulated primarily by the movement and posture of the body itself. Visceral sensations underlie such experiences as hunger, nausea, and sexual feelings. Clearly, there are more than five human senses (*see* FEELING, PSYCHOLOGY OF: *Theory of Feeling;* HUNGER AND THIRST).

H. L. F. von Helmholtz (*q.v.*) suggested that sensory experience be divided into modalities according to qualitative criteria. Sensory qualities within a single modality were to be those that fall in an uninterrupted continuum: for example, colour, where oranges merge into reds and yellows, and grays form a continuum between black and white. Discrete qualities for which no intermediates exist were to be placed in separate modalities.

The number of modalities by Helmholtz's definition cannot be specified with precision. Visual sensations form one such modality; all hues (as well as blacks, whites, and grays), brightnesses, and saturations can be represented by a continuous solid figure (*see* COLOUR). Audible tones constitute a continuum for pitch (*see* PITCH, MUSICAL). Smell (olfactory sensation) is more complex. Hans Henning's researches (1915) led him to believe that all olfactory qualities could be represented on the surface of a triangular prism, with fragrant, spicy, ethereal, resinous, putrid, and burnt odours at the six corners. Thus in his system smell is a single modality. Henning also placed the principal gustatory or taste qualities (bitter, sour, salt, and sweet) at the corners of a tetrahedron, and unified them as a single modality, asserting the existence of intermediate gustatory sensations. What are popularly called flavours depend heavily on odours perceived when food vapours ascend to the nose from the mouth (*see* FLAVOUR). It is doubtful whether intermediate qualities can be found among the principal cutaneous qualities (pressure, pain, warmth, and cold). Some have maintained that all deep sensibility (from muscles and joints, viscera, inner ear) reflects pressure-pain patterns and adds nothing new to the organism's repertoire of sense qualities.

Modern classification tends to be based less on verbally described experiences than on discriminability of stimuli as related to physiological mechanisms of separate sense organs and their associated neural systems.

Attributes.—A sensation is characterized by attributes, conscious dimensions along which it can vary independently; the chief attributes are quality, intensity, extensity, and duration.

Sensations are generally identified and named by their qualities; for example, red, blue, fragrant, putrid, sweet, bitter, tickle, ache. Any of these qualities can vary in intensity. Tones can be soft or loud, odours faint or strong, pains mild or excruciating. It would seem that visual sensation has two intensive attributes, brightness and saturation. A red or gray sensation may be light or dark; that variation is brightness. Red may also vary in saturation, the intensity of redness as opposed to weakness or grayness, without becoming either lighter or darker. When most people speak of bright red, they usually mean highly saturated red.

Visual and tactual sensations have extensity; space perception is based on this characteristic. There is also convincing evidence that tones are sensed to vary along a kind of extensity dimension called volume. Low tones tend to seem large, high tones small; loud tones tend to appear large, faint tones small. Hence a faint low tone may be matched in size to a loud high tone.

All sensations have duration (protensity) and can be compared in terms of how long they appear to last.

In the 19th century it was supposed that attributes of sensation must correspond to dimensions of the stimulus. However, most of the attributes depend on joint variation of two or more dimensions of the stimulus. For instance, while the loudness of a tone varies mainly with the energy dissipated in the vibration of the source, it also depends on frequency of vibration. A very low-pitched (or high-pitched) tone requires more energy than does a tone in the middle range for the two to appear equally loud. Apparent pitch depends primarily on frequency, yet apparent pitch will alter slightly when the energy of vibration is changed and frequency is kept constant. Thus attributes of tone (pitch, loudness, and volume) can be altered by varying the frequency and energy of the stimulus (*see* SOUND: *Acoustic Reception*).

Sensitivity.—The accuracy with which differences in sensation attributes can be discriminated is measured by determining absolute and differential thresholds. An absolute threshold marks the limit of some sensory continuum; *e.g.*, the lowest or highest audible tone, the limits of the visible spectrum in terms of wavelength, and the least noticeable intensity of any sensation. A differential threshold is the just noticeable difference (j.n.d.) between two stimuli. Since sensitivity varies from moment to moment, every threshold is statistically defined as the average value of a stimulus difference resulting from a number of judgments; *i.e*, the difference that is sensed just as often as it is not.

Differential threshold for intensity is often expressed as a Weber fraction (the ratio of j.n.d. to stimulus intensity). If the light from 51 candles is reported five times out of ten by a given person as perceptibly brighter than 50 candles when intensity is increased step by step from well below 50 candles to well above, the observer's differential threshold for this intensity is 1 candle, and his Weber fraction is 1/50 or 0.02. Weber's law assumes this fraction to be constant at all intensities; *i.e.*, the j.n.d. would be 10 candles for a stimulus of 500 candles, and 0.1 candle at 5 candles. The law fails to hold exactly, however, especially at lower intensities. Different people have different thresholds. Typical average determinations of the minimal Weber fraction for trained adults are as follows: subcutaneous pressure 1/77; visual brightness 1/62; weights lifted by hand 1/53; tones 1/11; smell of rubber 1/7; taste of salt 1/5 (*see* PSYCHOPHYSICAL METHODS).

Determinations of absolute intensity thresholds show that sense organs are extremely sensitive under optimal conditions. A barely visible star delivers to the eye about 10^{-8} microwatt (1/100,000,000 millionths watt). Tone can be heard at some frequencies when the eardrum moves somewhat less than 10^{-9} cm. If the ear were a bit more sensitive, people probably could hear the random movements of air molecules.

Physiology.—Sensory physiology investigates mechanisms that translate stimuli into nerve impulses and brain mechanisms that mediate discriminative responses.

Just as a microphone (*q.v.*) translates sound waves into electrical waves, sense organs are transducers that translate stimuli into nerve impulses. Each sense organ is selectively most sensitive to a specific form of energy called its adequate stimulus. Mechanoreceptors initiate sensory nerve impulses when they are mechanically deformed; these include pressure, kinesthetic, and vestibular receptors, as well as the receptor cells in the cochlea of the inner ear. The skin also contains thermoreceptors (not unequivocally identified in the 1960s) that respond to changes in temperature. Sense organs of taste and smell are chemoreceptors; their adequate stimuli are chemical properties of sapid and odorous substances. The receptor cells (rods and cones) of the retina are photoreceptors. It has been estimated that absorption of one quantum of light by the photochemical substance in a rod is sufficient to discharge it. Many more impulses, however, are required to produce a sensation of light; *i.e.*, discrimination of the presence or absence of a flash of light. Other sensory structures do not mediate awareness, but instead elicit important reflexes. For example, mechanoreceptors in the large artery (the aorta) leading from the heart detect, signal, and act to regulate the level of blood pressure (*see* CIRCULATION OF THE BLOOD: *The Nervous Regulation of the Heart Beat*).

Neural structure and activity are used to account for differences in perceived sensory quality. The primary quality distinctions are those among modalities; *e.g.*, colour, tone, odour, and taste. Ancient Greeks believed that objects give off faint copies of themselves that are conducted to the mind (*see* DEMOCRITUS: *Perception and Knowledge*). Some such view was still prevalent enough in the early 19th century for Johannes Peter Müller (*q.v.*) to react against it with his theory of specific nerve energies. Müller held that there are five kinds of sensory nerve, each of which carries its own specific kind of energy. He argued that the mind does not perceive objects themselves, but the quality of neural impulses the objects excite. He noted that any sensory nerve always gives rise to its own peculiar quality; thus pressure on the eyeball (clearly not the adequate stimulus for visual sensation) yields a perceived pattern of light. Later, when all neural impulses were found to have identical electrical qualities and sensory centres in the brain had been discovered, the modern view of sensory quality developed. In the 1960s there seemed to be no better theory of modal quality than the gross statement that there is a specific brain area for each sensory modality (*see* PSYCHOLOGY, PHYSIOLOGICAL).

The use of microelectrodes to record electrical potentials from individual neurons permits direct study of how the nervous system encodes sensory information. The technique has revealed ganglion cells in the retina that discharge only to stimulation from a relatively narrow band of wavelengths of light (the colour sensors); others show a much broader response sensitivity to wavelength (light sensors). Some fibres in the optic nerve discharge during stimulation; others activate only briefly at the beginning and end of a flash of light; a third type responds briefly only at the cessation of the stimulus. Microelectrode studies of other modalities indicate a similarly complex situation.

Recordings from single cells in the visual system of the brain suggest even more complicated encoding principles. Some populations of neurons in the cat's visual brain cortex are activated by retinal excitation from a stimulus object in the form of a line held at a given angle from the vertical. If the angle of the stimulus line is changed, new groups of brain cells are activated. Apparently some of the cat's cortical cells "see" only straight lines across the retina, and only when the lines are at specific angles. In the frog's optic tectum (part of the midbrain) there are cells that discharge only in response to a small moving spot on the retina. Apparently the way in which the nervous system encodes sensory information involves much more than simply the place or region to which the nerve fibres go; encoding may be in terms other than basic attributes derived from discriminative responses.

Sensed intensity seems definitely to depend upon amount of neural excitation. Since a single nerve fibre operates under the All-or-None Law (*q.v.*), giving rise either to its maximal excitation or to none at all, neural mediation of intensity differences requires explanation. When an increase in stimulus intensity at the sense organ is transmitted to the brain, sometimes the number of transmitting fibres is increased, and sometimes the rate at which successive impulses are sent along each fibre is increased; often both principles work together.

In considering extensity, note that in vision a point-to-point correspondence of the retina with the visual brain is well established. This correspondence is topological; *i.e.*, the order of points in the retinal field matches a corresponding order in the brain, but shapes and sizes need not be the same in the two (*see* GEOMETRY: *Topology*). The spatial order of retinal excitation thus is preserved in the brain; this is one way in which extensity values of sensation are coded.

It is assumed that tactual perception of space is mediated in a similar manner. Like the retina, the body surface is projected topologically on the cerebral cortex. Nerve fibres in the spinal cord are sorted into separate bundles according to modality (*e.g.*, pressure, pain, and temperature from the skin). When the projection fibres from the skin reach the brain cortex, however, they are arranged, not according to modality, but spatially in terms of a projective map of the surface of the body. In general, spatial difference in perception suggests the existence of spatial difference in cerebral excitation. Since the different modalities of the skin senses seem not to be separated on the cortex, this indicates that modality-specific information is also coded in other than spatial terms.

How the brain mediates sensations of duration was not known in the 1960s.

SENSITIVE PLANT: *see* MIMOSA.

SENTA, a town in the autonomous region of Vojvodina, in the Socialist Republic of Serbia, Yugoslavia, lies on the Tisa River, 23 mi. (37 km.) SE of Subotica. Pop. (1961) 25,062. The town has a law court, a museum, and several schools. Agriculture and the manufacture of consumer goods (soap, candles, and furniture) are the main occupations. The town is connected by rail and road with Novi Sad and Subotica, and with Hungary and Rumania. Senta was mentioned in 1216 and from the mid-16th century it was in Turkish hands. In 1697 Prince Eugene of Savoy defeated the Turks there. In 1918 it became part of Yugoslavia. *See* also SERBIA. (V. DE.)

SENTINUM, an ancient town of Umbria, Italy, lying to the south of the modern town of Sassoferrato, in the low ground. The foundations of the city walls are preserved, and a road and remains of houses have been discovered, including several mosaic pavements. In the neighbourhood the battle took place in which the Romans defeated the combined forces of the Samnites and Gauls in 295 B.C. It was taken and destroyed in 41 B.C. by the troops of Octavian, but revived under the empire. The people of Sentinum had many of the rights of Roman citizenship.

SENUFO, a group of closely related indigenous tribes of northern Republic of Ivory Coast and southeastern Republic of Mali (*qq.v.*), numbering about 750,000 in the 1960s. They speak at least four distinct languages (Palaka, Dyimini, and Senari in Ivory Coast; Suppire in Mali) which belong to the Gur branch of the Niger-Congo language family (*see* AFRICAN LANGUAGES). Within each group, numerous subdivisions use their own names for the people and language; the name Senufo is of external origin. Palaka separated from the main Senufo stock well before the 14th century A.D.; at about that time, with the founding of the town of

Kong as a Bambara (*q.v.*) trade-route station, the rest of the tribe began its migrations to the south, west, and north, resulting in the present divisions.

Senufo peoples are agricultural, major crops including corn and millet. Their farms cluster around villages of small mud-brick houses, thatched in the south but with flat roofs in the drier north. The domestic unit is the extended family: a patriarch with his sons and their wives and children. Marriage is by parental arrangement; polygyny (*q.v.*) is fairly common. Inheritance goes to a brother by the same mother, or to other members of the mother's family. Initiation rites for adolescents are the introduction to adult tribal responsibilities. Burial is in a village plot; the body is wound in cloth with one hand exposed, and buried in a niche in the wall of a grave, which is then sealed with bricks.

Senufo are among the outstanding musicians of Africa. They use marimbas, tuned iron gongs, a variety of drums, horns, and flutes; marimba and drum orchestras are common.

See W. E. Welmers, "Notes on Two Languages of the Senufo Group . . . ," *Language*, vol. 26 (1950); R. Goldwater, *Senufo Sculpture from West Africa* (1964). (W. E. WE.)

SENUSI (SENUSSI; Arab. SANUSI), in a strict and narrow sense a member of the Sanusiya, an Islamic order or fraternity established in Arabia and North Africa in the 19th century by Sayyid Mohammed bin 'Ali al-Sanusi, a sharif (descendant of the Prophet) from Mostaganem, Alg. It is one of a large number of Sufi or dervish orders (*see* SUFISM), all of which require from their members observances of one sort or another, such as recitation of litanies, in addition to the duties incumbent on every Muslim. There has always been a tendency for new orders to form out of older ones as eminent teachers make additions to earlier teachings and persuade others to follow the new rites and rules. Each has claimed orthodoxy and authority by citing the chain of his spiritual succession from some admired theologian of the past whose orthodoxy was not questioned. The Sanusiya was on the whole conservative, conventional, rational (not ecstatic), and puritanical. It was a reformist movement aimed at a return to the simple faith and life of the earliest days of Islam. It was also a missionary order which sought to instruct the Bedouin and persuade them to live a life more in accordance with the commands of the Koran and the teachings and example of the Prophet Mohammed than they were wont to do. It aimed further at converting the pagans or semipagans of the Sahara and central Africa.

The Sanusiya.—Sayyid Mohammed bin 'Ali al-Sanusi (1791–1859), generally spoken of as al-Sanusi al-Kabir, the Grand Senusi, to distinguish him from other notable members of the Senusi family, was a pupil during his residence at Mecca of another well-known Sufi teacher, Sayyid Ahmad bin Idris al-Fasi (d. 1837), the head of the Moroccan Khadiriya order, a branch of the Shadhiliya order, and later the founder of a new suborder of his own, the Idrisiya. On Sayyid Ahmad's death his two chief disciples founded two new orders, the Mirghaniya, which became prominent in the Sudan, and the Sanusiya, the head of which, Sayyid Mohammed Idris, grandson of the Grand Senusi, became king of Libya in 1951 (*see* IDRIS I). The Grand Senusi first established his headquarters at Mt. Abu Qubais, near Mecca, in 1837, and this year is regarded as the official date of foundation of the order.

Henceforth the word "Senusi" ("Sanusi") is used in a wider sense. Members of the Sanusiya in the narrower and strictly religious sense, *i.e.*, those who practised its rites, were few in number. The vast majority of people called Senusi were personal followers of the Grand Senusi and his family, an attachment which in North Africa was eventually to develop into a political relationship. It does not appear that the Grand Senusi originally intended to direct his activities toward North Africa. The new order was making rapid progress among the Bedouin of the Hejaz when it aroused the enmity of various authorities in Mecca, and the Grand Senusi felt it expedient to depart, accompanied by a number of his disciples, for his native land; but, hearing of French advances in Algeria, he turned back to Tripolitania and then to Cyrenaica, where in 1843 he founded the mother lodge, *al-zawiya al-Baida* (*zawiya*, "lodge"). Eventually he moved the centre of the order to the distant oasis of Jaghbub (Giarabub), possibly to avoid too much attention from the Turkish administration then in control of Cyrenaica, and there he founded an Islamic university which became famous for its library. From Jaghbub he intensified his propaganda in the Sahara and the Sudan. He died at the oasis on Sept. 7, 1859. The Sanusiya order was by that time the dominant order, outside the towns, in western Arabia and in North Africa from the Nile Valley to the borders of Tunisia and from the Mediterranean to the Sahara.

Under his son and successor, Sayyid Mohammed al-Mahdi (1845–1902), the order expanded considerably, particularly into the Sahara and the Sudan, for which reason he moved its seat to the remote and isolated oasis of Kufra in 1895. This expansion of his theocratic empire clashed with French interests, for at the time the French were making rapid military and political advances into the Sahara. Sayyid al-Mahdi died in 1902. At the time of his death almost all the Bedouin and the oasis dwellers under their influence in Cyrenaica and the Sirtica and most of those in the Western Desert of Egypt were adherents of the order, and it had also a considerable following in southern Tripolitania, Fezzan, central Sahara, and the Hejaz. In all these regions there had been planted lodges of the order, over 140 in all. Then its fortunes declined, mainly, as will be seen, because its empire was attacked by the French in the Sahara and by the Italians in Cyrenaica and Tripolitania, while Wahhabi rule in Arabia curtailed its influence and prevented further expansion there. Sayyid Ahmad al-Sharif, the third head of the order and Sayyid al-Mahdi's nephew, was too occupied in meeting these threats in Africa as leader of the Sanusiya militant to be able to devote himself to anything else. From 1902 to 1912 he was resisting the French in the Sahara, from 1912 to 1918 he was directing the Bedouin resistance to the Italians, and later to the British, in Cyrenaica, and from 1918 to 1933, the year of his death at Medina in Arabia, he was an exile. From 1918 therefore, though Sayyid Ahmad never formally renounced headship of the order, effective control of it was in the hands of his cousin Sayyid Mohammed Idris, son of Sayyid al-Mahdi, who later as King Idris I of Libya had the dual position of head of the order and head of the state.

Organization of the Order.—The creation of an empire of the size it was in the time of Sayyid al-Mahdi and among a people so intractable as the Bedouin was a remarkable achievement. It was done through an organization which, however simple, served the purpose of unifying a number of different tribes and peoples through their common acknowledgment of loyalty to the Senusi family. The head of the order was advised by a small inner circle known as the *Khawass*. Other sheikhs of lodges and other persons who lived in them and practised the rule of the order were called *Ikhwan* ("brothers"). Apart from this very small category of persons, the adherents to the order were *muntasabin*, illiterate people who identified themselves with its interests. In every region where the Grand Senusi and his followers gained influence it was consolidated by the building of *zawiyas* at the request of the local population. They were placed at points of political or commercial significance, often in Cyrenaica where there had been settlements in Greco-Roman times. They may have been rather simple structures but they were imposing in regions where a tented people roamed. The local population, having asked for a *zawiya*, endowed it with land, wells, springs, or date palms, and the inmates lived by exploiting these donations, by their own labour, and on tithes and other contributions of money, goods, transport, and labour. Each lodge lived on its own revenues and also sent a surplus to maintain the centre of the order at Jaghbub or Kufra. The lodges were more or less autonomous in day-by-day running of affairs, but the sheikh of each was appointed by the head of the order and was responsible to him, though the post tended to become hereditary. Through its lodges the order rendered services to the people who maintained them. Each was a small centre for propagation of the faith, for simple schooling, and for settlement of disputes, and provided shelter and hospitality for travelers and asylum for those in jeopardy. They were small islands of civilization in what was then a barbaric sea.

Establishment in Cyrenaica.—It was in Cyrenaica that the order became most firmly established and for longest retained its

influence, and also where its organization and history have been most closely studied. Several circumstances favoured it there. Cyrenaica was isolated by deserts to south, east, and west. The country was not dominated by the towns, and the Turkish administration, which operated from such small towns as there were, exercised very little control over the interior. The Sanusiya therefore did not have to compete with any rival power, and the services it rendered were not being supplied by any other organization. Also the Bedouin were used to holy men, marabouts, coming from the west on pilgrimage to Mecca. Many settled in Cyrenaica where their tombs, familiar landmarks in the countryside, are venerated by the Bedouin; and it was further greatly to the advantage of the order that the sheikhs of its lodges were usually foreigners from the Maghreb (Maghrib), for this meant that they were not involved by sectional loyalties in the feuds and disputes endemic to Bedouin society and hence were suitable arbitrators. Also, whether that was his purpose or not, the Grand Senusi, by making Jaghbub the headquarters of the order and the residence of its head, ensured that it could not, by territorial location, be identified with any one tribe or tribal section and thereby arouse the jealousy of others.

But perhaps the main reason for the success of the order in Cyrenaica was that the Grand Senusi was able to integrate the *zawiya* organization with an already existing tribal system. There were nine noble, what are locally called *Sa'adi*, tribes and several client, or *Marabtin*, tribes, each divided into sections. In every main tribal section the order established one of its lodges, so that the more fractionized a tribe was the more lodges it tended to have. Altogether there were 45 *zawiyas* in Cyrenaica proper. In this manner the order was planted in every political segment of the country, and each segment, through its *zawiya*, participated in the order. The tribal system and the Sanusiya organization interpenetrated. This situation among the Bedouin and attached oasis folk may be contrasted with that obtaining in the towns. In the small towns of Cyrenaica eight other dervish orders were represented, only two of which had any representation among the Bedouin, and that slight. The lodges of these orders—and this applies also to the urban lodges of the Sanusiya—were little more than clubs for religious exercises and social insurance. They had no political significance because they were both small in membership and lacked cohesion and unity of direction. Their political ineffectiveness may be said to have reflected the individualism of urban communities, people's interests being confined to small quarters and even single streets, as contrasted with the solidarity and wider loyalties of tribal life.

Political Functions.—The Sanusiya had some proto-statal functions during Turkish times. So long as there was a reasonable amount of security and taxes were, at least sometimes, paid, the Turks left the Bedouin to their own devices. This meant that the order performed some services which are usually a governmental responsibility and also that it acted as intermediary between the Turkish administration and the tribes. The lodges in Cyrenaica were separated by Egypt from those in Arabia, and the Sanusiya's Saharan and Sudanese empire was crumbling year by year before fresh French advances. Yet the effect of the struggle that followed the Italian landing on the Cyrenaican coast in October 1911 was to accentuate the political functions of the Sanusiya.

Wars With Italy.—From the beginning of the Italo-Turkish War (*q.v.*), sheikhs of the lodges organized the tribes to aid the Turkish forces stationed in the country in their resistance. It was primarily a war between Italians and Turks, but the Bedouin gave support to their fellow Muslims. Being unable to reinforce their garrisons in Libya and facing serious troubles in the Balkans and in Yemen, the Turks made peace in October 1912 and promised to withdraw all armed forces from Libya. In the event, however, they did not withdraw their troops from Cyrenaica. Meanwhile Sayyid Ahmad had arrived at Jaghbub from Kufra and there met the Turkish commander, Enver Bey, who asked him to continue resistance in the name of the sultan; in the following year Sayyid Ahmad took charge of operations. At this point it became an Italo-Senusi war, the Senusi fighting in the name of the Sanusiya order and under the direction of Sayyid Ahmad and the sheikhs and brothers of the order. Most of the Turkish forces eventually departed for Egypt in late 1913 or very early in 1914. When Italy entered World War I in 1915 on the side of the Allies the Senusi thereby became involved with British forces in Egypt and were finally routed by them in February 1916. Sayyid Ahmad fled to the oasis of al Dakhla (ad Dakhilah) in Egypt and finally to Turkey in September 1918.

After prolonged negotiations a *modus vivendi* was agreed upon, Sayyid Idris representing the people of Cyrenaica in the discussions with the British and Italians which led to it. The political significance of these negotiations lay in the fact that, since they could not be carried on with an acephalous body, the only person who in the circumstances could speak for the people of Cyrenaica was the head of the Sanusiya, who throughout the discussions claimed sovereignty for the order over the whole country, over most of which it exercised control, both political and military, at the time. The truce resulted in an uneasy Italo-Sanusiya condominium, during which the Sayyid was accorded by the Italians (the British had vanished from the scene) the somewhat ambiguous title of amir and various other recognitions of political status as distinct from that which he had as leader of a religious fraternity.

When it became clear that the Italians intended to end the truce as soon as it suited their convenience, the amir fled in December 1922 to Egypt, where he continued, as far as he was able, to represent the Senusi resistance when the Italians began a further attempt to subjugate them in March 1923. This second colonial war lasted till 1932, Senusi-Bedouin forces in it being led by Sidi 'Umar al-Mukhtar, a Sanusiya sheikh who throughout conducted operations as representative of the order and of its head, the amir, thereby further enhancing the political role of the order and marking a further step in its secular development. The first war was fought in the name of the sultan and caliph, the second in the name of the Sanusiya. In the bitter and long-drawn-out suppression of the Bedouin and in the measures they took afterward, during the period of colonization, the Italians aimed at the complete destruction of the order: *delenda est Sanusiya* (*see* LIBYA). The *zawiyas* were demolished or fell into ruins, their sheikhs were scattered or exiled, their estates were confiscated, and the head of the order was in asylum in Egypt. The order was to all intents and purposes eliminated.

King Idris I.—When Italy entered World War II in June 1940 the amir Idris offered the services of his people to the British cause, and they played an ancillary part in the operations which took place in the Western Desert. In 1943, when the fighting was over, the amir reentered Cyrenaica, just a century after his grandfather had founded his first *zawiya* there; but he did not return as head of a religious fraternity, though he was that of course, but rather as a head of state. The Italians, by destroying the Sanusiya organization, had made yet more evident the political status of its head. When in 1951 the amir became King Idris I of Libya (Tripolitania, Cyrenaica, and Fezzan), the order, which had begun as a religious movement and developed into a political one could not be reconstituted to exercise political functions in the new state.

SEONI, a town in Madhya Pradesh, India, and the administrative headquarters of the district of the same name, lies on the Nagpur-Jabalpur road, about 80 mi. (129 km.) N of Nagpur and on the branch line of the Satpura Railway from Nainpur to Chhindwara. Pop. (1961) 30,274. The town has a government high school and a girls' school. Seoni provides a market for a large area of the Satpura Hills region; it is also a weaving centre and is noted for the manufacture of lac bangles.

SEONI DISTRICT has an area of 3,376 sq.mi. (8,744 sq.km.) and a population (1961) of 523,741. A large part of the district is forested, yielding teak, bamboo, lac, and myrobalans. The chief crop is wheat, but gram, rice, cotton, and oilseeds are also important. In the south, Kurai is the centre of wholesale trade in

teak, which is exported to Kamptee in Nagpur district, Maharashtra. (D. G. Na.)

SEOUL (Kyongsong; Jap. Keijo), the capital of the Republic of Korea, at 37° 34′ N. and 127° 6′ E. and an altitude of 120 ft., is 25 mi. from Chemulpo (*q.v.*), its seaport. Pop. urban area (1960) 2,445,402. It lies in a basin among granite hills of 2,000 to 3,000 ft., remarkable for their craggy peaks and barren slopes. Seoul was the capital of Yi dynasty (1392–1910). Shortly after its founding, a stone wall pierced by eight gates, 20 to 30 ft. in height and about 11 mi. in circuit, was built upon the natural base of the hills. The city is 3 mi. N. of the Han river, upon which it depended for its major water supply in early days. The northern part of the old city against the highest hills was the site of the wall-enclosed palace grounds of the Yi family. It was laid out in wards after the pattern of Peking. Above the flat skyline of single story houses rose the city gates and palace walls.

With the opening of Korea to the outside world in 1876 and particularly after the annexation of Korea to Japan in 1910, many changes came to the city. The city walls were not preserved, and the gates became isolated symbols of the past. A railroad centre was developed between the south gate and the Han river; residential suburbs sprang up, some of them across the Han. An imposing granite Japanese government-general building was built on one of the palace grounds; other brick and stone buildings for bank and commercial concerns modified the appearance of the city. A streetcar system was developed. A university was established on another palace ground in the northeast of the city, and other educational establishments were opened. The Christian missionary influence is demonstrated by the many churches, including the imposing Roman Catholic cathedral.

After World War II, with Korea divided by the 38th parallel, Seoul became the centre of the U.S. military government and on Aug. 15, 1948, the capital of the Republic of Korea. Refugees from Communist-dominated North Korea flooded into the city. New buildings were constructed and the population spread into the suburbs.

Seoul was an immediate target for attack at the outbreak of the Korean war and was occupied by Communist forces on June 28, 1950, three days after they crossed the 38th parallel. The bridge across the Han was dynamited by Republic of Korea (R.O.K.) forces as a delaying action. The UN forces re-entered Seoul on Sept. 29, 1950, but it was occupied again by Communist troops on Jan. 4, 1951, though it was retaken on March 14, 1951. Great damage was inflicted, especially to the major buildings. After 1951 reconstruction progressed, broad streets were laid out and new buildings were erected. Seoul again became the political, industrial, financial and cultural centre of the republic. It forms a special governmental unit, equivalent to a province. (S. McC.)

SEPARATION OF POWERS. The separation of powers, an essential feature of constitutional government, was classically expounded by Montesquieu in a celebrated chapter of the *Esprit des lois* (1748). In his discussion of the English constitution, he drew a sharp, logical distinction between the legislative, the executive and the judicial powers and insisted that they should be handled by separate and distinct bodies. A variant of this doctrine had been previously stated by the English philosopher John Locke. It would appear ultimately to have derived from ancient and medieval concepts of mixed government (*see* below).

Locke was concerned with making sure that only one power, the legislative power, be divided between the king and parliament. Before him, the 17th-century political theorist James Harrington had advocated a more abstract notion of a necessary balance of power, which he elaborated in his *Oceana* (1656). Harrington's work shows more clearly than that of the later theorists how the separation of powers derived from the theory of mixed government. The advantages of combining monarchy, aristocracy and democracy had been a commonplace of political thought ever since Aristotle and Polybius. Indeed, it was a doctrine which the most diverse writers agreed upon, including St. Thomas Aquinas and Marsilius of Padua, Machiavelli and the Machiavellians and Monarchomachs. But it lacked precision until it was transformed into the doctrine of the separation of powers.

Following Montesquieu, the separation of powers was given institutional expression in many constitutions, notably the United States constitution of 1787, the French constitutions of the Revolutionary period and various monarchical constitutions of western Europe in the post-Napoleonic period. It was most fully elaborated in the United States by John Adams, who refined it by a rather flexible doctrine of "checks and balances." Kant gave it its most abstract philosophical form, by interpreting it as the institutionalization of a logical syllogism.

In the light of subsequent constitutional experience, it became clear that the triple separation of powers was only one means of solving a broader constitutional problem: how to insure the restraint of governmental power by dividing such power without carrying division to an extreme incompatible with effective government. Federalism (*see* Federal Government), the division of power between coexisting territorial jurisdictions, was another means of achieving this purpose. When seen as part of this broader design, the classical functional division of power loses some of its rigidity and dogmatic purity. Any comparative study of modern constitutional systems discloses a great variety of arrangements, as illustrated by the very divergent treatment of the judicial power in the U.S., British, French and Swiss systems, and the organizing and structuring of the legislative power is a problem whose solution likewise varies according to circumstances.

The concept of the separation of powers was sharply attacked, in the name of both democracy (*q.v.*) and efficiency, by fascists and communists who radically rejected the idea of dividing governmental power and insisted upon the need of concentrating it in the hands of ruling party groups dedicated to the revolutionary transformation of society. Other critics, from Jeremy Bentham onward, objected to the inhibiting effect of the separation of powers, insisting that it does not actually operate, that it cannot be effectuated. Thus J. Allen Smith, in *The Growth and Decadence of Constitutional Government* (1930), a penetrating critique focused upon the serious disequilibrium resulting from large-scale modern industry, announced the impending demise of the time-honoured scheme. However, experience with the totalitarian dictatorships of the interwar and post-World War II era persuaded many to reconsider. One conclusion was clear: constitutional democracy presupposed a balanced system of divided powers, for only within such a system could the citizen hope to enjoy a measure of independence and freedom through a guarantee of civil liberties. (C. J. Fr.)

SEPARATOR, MAGNETIC, a device for the separation of iron or steel and of feebly magnetic ores, for the purification of materials and the prevention of damage to machines. There are a great many designs of machines, including numerous continuous feed types for handling large quantities of material. One common form has a rotating drum carrying magnets on which the material falls; the magnetic portions cling to the drum and are then brushed off. Another type has a belt passing over two pulleys, the belt being fitted with magnetized feelers. A larger type with long conveyor belt is employed in mining practice for the separation of weakly magnetic minerals from nonmagnetic, such as wolfram from tin ores. A series of magnets above the belt deal with the material in its passage below them. Some machines are portable and may be made at dumps or tips, while for treating house refuse a rather large fixed separator supplied by a conveyor belt lifts tins and other iron pieces out of the waste and places them automatically into a chute. Used foundry sand can be dealt with by a machine which recovers small splashes of iron, brads, chippings, etc., and also sieves and grades the sand ready for use again. Mixed iron and brass turnings are separated in the rotary drum class of apparatus, while some separation, as for the pottery and china trade, is effected in a wet trough device. Many kinds of powders and seeds, cocoa beans, tea, tobacco, etc., are treated by a magnetic separator. Substances that have to go through a crusher are treated magnetically to avoid the risk of damage by "tramp" iron.

SEPHARDIM, ASHKENAZIM, AND ORIENTAL JEWS are the three major divisions of the Jewish people.

The Sephardim are the Jews whose ancestors lived in the Mid-

dle Ages in Spain (*Sepharad* in Hebrew). After their expulsion from Spain (1492) they settled in France, Holland, England, Italy, the Balkans, Turkey, Palestine, and North Africa as well as overseas, where they have continued to live. They preserved everywhere their own customs, religious ritual, and the Ladino (Judeo-Spaniolic) language, a form of medieval Spanish with some Hebrew terms, written in Hebrew characters. The Sephardim numbered about 500,000 by the 1960s.

The Ashkenazim (from the Hebrew *Ashkenaz*, Germany) are the Jews whose ancestors lived in the Middle Ages in German lands and migrated thence to east and west Europe, and, in the 19th and 20th centuries, overseas. Their customs and religious ritual differ markedly from those of the Sephardim. Up to the end of the 19th century most Ashkenazim everywhere spoke Yiddish or Judeo-German, a form of medieval German with a certain percentage of Hebrew expressions, written, like Ladino, in Hebrew characters (*see* YIDDISH LANGUAGE). The total number of Ashkenazim in the 1960s was estimated at 11,000,000, including almost all the 5,600,000 Jews in the U.S. and some 3,000,000 in the Soviet orbit.

The Oriental Jews, more varied in their ethnic characteristics than either the Sephardim or the Ashkenazim, are the descendants of Jews who, following the Assyrian, or Babylonian, or Roman exile from Palestine, settled in countries of the Middle East and North Africa. In Arab lands (Lebanon, Syria, Palestine, Iraq, South Arabia, Egypt, Libya, Tunisia, Algeria, and Morocco) they acquired, and have retained, Arabic as their mother tongue; in Persian-speaking lands (Iran, Afghanistan, Bukhara), Persian; in Kurdistan, Neo-Aramaic. From Iraq Oriental Jews moved on to India, and from Afghanistan and Bukhara into other parts of Central Asia and even into China. In some Oriental Jewish communities (notably those of Yemen and Iran) polygyny has been practised. Following the establishment of Israel in 1948 practically all the Yemenite, Iraqi, and Libyan Jews, and major parts of the Turkish, Tunisian, Algerian, Moroccan, and Syrian Jewish communities were resettled in Israel. The Oriental Jews numbered in the 1960s about 1,500,000.

Some minor Jewish groups do not fit into the above threefold division. These comprise the 2,000-year-old Italian-speaking Jewish communities; the even older Greek-speaking Jewish communities (mostly destroyed during the Nazi occupation); the Falashas (*q.v.*) or black Jews of Ethiopia; and the Bene-Israel (*q.v.*) or black Jews of India, of obscure origin. (RA. P.)

SEPIA, a semitransparent dark-brown pigment obtained from the ink sacs of cuttlefishes and squids. The sacs (which are speedily removed on capture and dried to prevent putrefaction) are dissolved in dilute alkali; the solution is filtered; and the pigment, precipitated with dilute hydrochloric acid, is then washed, filtered, and dried. The chemically inert pigment is fairly permanent and is used as a drawing ink and as an artist's watercolour, particularly in monochrome. (J. KA.)

SEPIK RIVER, one of the largest rivers on the island of New Guinea (*q.v.*), rises in the Victor Emmanuel Range, part of the great central cordillera, and for much of its course flows eastward following a great structural depression between the cordillera and the coastal ranges, emptying into the Bismarck Sea. The river is about 600 mi. (966 km.) long and is navigable for more than 300 mi. (483 km.) for vessels drawing 13 ft. (4 m.) of water, but much of this part of the course consists of a wilderness of sago and nipa palm swamp covering hundreds of square miles, while extensive mangrove swamps occur at the delta. As with all the great rivers of New Guinea, there are no large settlements along the course of the Sepik, and the whole of the lower basin is very sparsely populated. (D. W. F.)

SEPSIS means, literally, putrefaction or decay and implies illness from the absorption of noxious substances. It is too inexact a word to convey the specific meaning required by modern medical nomenclature and is used usually as a descriptive adjective (septic) to denote a special appearance or attitude. The word toxic is frequently used synonymously but it is not altogether correct. A toxin (*q.v.*) is a noxious protein that may be a plant extract, animal venom, or bacterial product. Toxins are introduced from without, whereas the victim of sepsis is carrying the responsible focus within his body. An example of this is a patient whose bowel is obstructed; he is absorbing back into his system products which normally would be eliminated.

Before bacteria were discovered and before the communicable nature of disease was known, putrefaction and fermentation were considered the basis of the septic state. Theodor Schwann in 1836 found that putrefaction was caused by living organisms and Louis Pasteur finally laid to rest the old belief.

Sapremia.—When dead protein material lies static within a hollow organ such as the intestine or in a body cavity, certain bacteria gain access to it. Access may be by direct inoculation, as with a needle or instrument used to evacuate the cavity, or by direct extension through membranes which are in contact with the outside. These bacteria are saprophytic; *i.e.*, they live and multiply in a necrotic environment and are incapable of invading healthy tissue. They are not pathogenic (capable of originating disease) in the human body. These bacteria multiply, use the dead protein for food, and elaborate waste products. The body absorbs these waste products and a state of sapremia, a form or subgroup of sepsis, is thereby set up. The condition is marked by loss of appetite and weight, depletion of energy, and slight to moderate fever—the usual clinical picture of chronic illness. If sapremia continues for a period of years, irreversible cellular changes such as amyloid degeneration may take place in the liver and kidneys particularly, thus making complete recovery, even with proper care, virtually impossible. Early diagnosis, prompt evacuation of the putrid contents under strict aseptic conditions, the prevention of secondary infection by pathogenic organisms during the application of dressings, and the building of an adequate protein and vitamin reserve will usually bring about complete recovery from the sapremic state.

Septicemia.—It is not always possible to know definitely by the symptoms that saprophytic bacteria are entirely responsible: other subgroups of sepsis must then be considered. Pathogenic bacteria may also invade the putrid cavity and from it gain access to the body. They are capable of living and multiplying in otherwise healthy tissue and originating a disease known as septicemia (blood poisoning). Exact diagnosis depends on identifying the organism; there is streptococcal septicemia, pneumococcal septicemia, typhoid septicemia, etc. Identification is usually made from cultures of the blood or of the discharge from the wound through which the bacteria entered the body. Unlike sapremia, septicemia is caused by bacteria that do not need to inhabit a large putrefying cavity. The originating site in septicemia is therefore difficult to locate. The highly virulent streptococcus, for instance, may gain entrance through a scratch or prick of which the person was barely aware. Occasionally, sudden "lighting up" of a focus inside the body, as an abscess at the root of a tooth or infected tonsils, sinuses, gall bladder, prostate, etc., is indicative.

Pyemia.—Another subgroup under the broad heading of sepsis is pyemia. As in septicemia, the bacteria causing pyemia are pathogenic but they are also pyogenic; *i.e.*, capable of local tissue destruction and pus formation. The most common pyemic organism is the staphylococcus. On gaining access to the bloodstream the bacteria are carried throughout the body, to become lodged finally in the small end arteries where they set up local abscesses in the bones, joints, lungs, brain, liver, and other tissues. Pyemia is a frequent disease of children and is the forerunner of an affliction of bone in childhood, acute osteomyelitis (blood-borne infection of bone).

Effect on the Body.—Bacteria, then, form the background of sepsis. Their effect on the body is both local and general and the intensity of the effect is determined by the virulence of the organism and the body's resistance. The local reaction is known as inflammation (*q.v.*). It is characterized by redness, swelling, increase in regional heat, and pain. These phenomena are the result of the stimulation and activation of nature's defenses. The rate of blood flow to the part is quickened and the white cells of the blood (defenders) are mobilized. The small blood vessels and capillaries become more permeable and permit an outpouring of cells and plasma into the involved tissues. If the invaders are

pyogenic bacteria, pus is produced. This is a combination of destroyed and liquefied tissue, blood serum, dead bacteria, and white blood cells. If the suppurating area has a sufficiently large adsorptive surface, the systemic effects are then produced, and these are those of the septic state. The symptoms of fever, chills, malaise, etc., are the result of the absorption of the broken-down tissue at the point of infection, or the result of toxins stored in the bacterial bodies and released after their death and destruction by the white blood cells.

Treatment.—Exact diagnosis of the subgroup of sepsis must first be made. The sapremic state usually can be traced to a cavity containing putrescible material under tension. When the tension is relieved and drainage is instituted, improvement will begin; but not until complete evacuation, sterilization, and obliteration of the cavity have taken place will a cure be effected. Evacuation is accomplished by incision and drainage. This allows the local defense forces to phagocytize (neutralize and destroy) the bacteria and render the cavity sterile. The reparative process then obliterates the cavity with scar tissue. Aside from general supportive measures no specific treatment need be used other than surgical drainage.

If a culture of the blood or discharge shows that pathogenic bacteria are present, surgery is not indicated until the infection is definitely localized. To cut into an area of diffuse infection is to risk opening more channels for invasion, and of breaking down the barriers nature has already set up to keep the infection localized. The involved part is rested and moist warm dressings are applied to increase the blood flow and prevent discharges from crusting and thus interfering with free drainage. Sulfa drugs and antibiotics are useful supplements.

Pyemia is treated similarly. Diagnosis of abscesses cannot be made nor treatment instituted until clinical signs are evident. Each abscess must be treated as a separate entity, and treatment will depend in great measure on the type of tissue in which the abscess is located. The best weapons for sterilization of the blood stream and prevention of abscesses are the antibiotics.

See also BACTERIA. (J. K. SK.)

SEPTARIUM, a subspherical concretionary body, an inch to a foot or more in diameter, found in some shales and characterized by an internal network of veins. *See* CONCRETION.

SEPTEMBER, the ninth month of the modern calendar, with 30 days. As is shown by its name (from Lat. *septem*), it was the seventh month in the early Roman calendar, which began with March. In the United States the first Monday of September is celebrated as Labour Day (*q.v.*), and the weekend in which it falls has become a major holiday, conventionally regarded as the end of the summer season. Michaelmas, the feast of the archangel Michael, is Sept. 29. An old saying runs, "If you eat goose on Michaelmas Day, you will never want money all the year round." The autumnal equinox occurs in this month. (F. R. WN.)

SEPTUAGINT, the earliest extant Greek translation of the Old Testament out of the original Hebrew, made during the 3rd and 2nd centuries B.C. for the use of the Jewish community in Egypt.

Legend and History.—The name Septuagint is derived from the legend that there were 70 (Lat. *septuaginta*, abbreviated as LXX), or rather 72, translators (six from each of the 12 tribes of Israel), who worked in separate cells, translating the whole, and in the end all their versions were found to be identical. The tradition that translators were sent to Alexandria by Eleazar, the chief priest at Jerusalem, at the request of Ptolemy II Philadelphus (285–246 B.C.), a patron of literature, first appears in the letter of Aristeas to Philocrates, probably written toward the end of the 2nd century B.C. but possibly making use of older material (*see* ARISTEAS, LETTER OF). This letter advocates merely a revised version of the Pentateuch, which must therefore have already existed in an earlier translation. The Septuagint does show traces of Egyptian origin, and it is probable that from various contemporary Greek translations made in several places those of the largest centres became the most important. Then, probably, the version used in Alexandria, the greatest centre of all, eventually superseded the others.

Analysis of the language of the Septuagint shows that the Pentateuch was the first part of the Old Testament to be translated, at about the beginning of the 3rd century B.C. This accords with the important place held by the Pentateuch in Jewish religion. The prophetic books of the Bible were translated into Greek in the 2nd century B.C., and the prologue to Ecclesiasticus, written *c.* 132 B.C., may imply that the third division of the Hebrew canon, the Writings or Hagiographa, already existed by then in Greek translation. It is not known how far translations of biblical books outside the Pentateuch obtained the authority of the synagogues.

The early Christian Church, whose language was Greek, used the Septuagint, not the Hebrew original, as its Bible, so it found in the Septuagint text the prophecies that it claimed were fulfilled by Christ. To Jewish eyes this was a misuse of the Holy Scriptures, and Jews therefore tended to cease using the Septuagint, particularly after the fall of Jerusalem to the Romans in A.D. 70, when normative Judaism restricted itself more and more to the Hebrew text of the Bible. A Greek translation was still needed, however, and the Jews attempted to replace the Septuagint by a new translation more in harmony with the stricter ideas of the period. The version by Aquila, as well as those of Symmachus and Theodotion (*q.v.*), fulfilled this need for a time.

The later history of the Septuagint lies entirely within the Christian Church. The authors of the New Testament drew their Old Testament quotations chiefly from the Septuagint, not the Hebrew, and the Septuagint was the Old Testament used by the Greek Church Fathers in constructing their theology. Origen (*q.v.*) in the 3rd century A.D. attempted in his *Hexapla* to check the degeneration of its text, which by then varied widely from copy to copy. Lucian of Antioch (*c.* A.D. 300) also consulted the Hebrew in order to make the Septuagint text more accurate. The Septuagint, not the original Hebrew, was the main basis for the Old Latin, Coptic, Ethiopic, Armenian, Georgian, Slavonic, and part of the Arabic translations of the Old Testament. The Septuagint has never ceased to be the standard version of the Old Testament in the Greek Church, whose liturgical texts are imbued with its language.

Contents.—The Palestinian collection of Old Testament books was fixed by Jewish authority in the 1st century A.D. The Septuagint contains all the books in this Jewish canon together with the extra books usually known as the Apocrypha (*see* APOCRYPHA, OLD TESTAMENT). The order of the books in the Septuagint differs from that of the Hebrew canon. Instead of the Jewish division into three—Law, Prophets (including history), and Writings or Hagiographa—the Septuagint has four divisions—Law, history, poetry, Prophets. The books of the Apocrypha are inserted where appropriate and do not form a separate group. This new division was perpetuated in the Western Church by way of the Old Latin version and the Vulgate and lives on in most modern translations of the Bible, save that in Protestant versions the Apocrypha is either omitted or grouped separately.

Language, Text, and Editions.—In vocabulary and grammar there is little to distinguish the Greek of the Septuagint from the Hellenistic Greek, known as Koine, of its period (*see* GREEK LANGUAGE: *Koine and Byzantine*). The syntax however betrays the Semitic character of the original in many ways, though this is not equally true of all the books: IV Maccabees, for example, which is not translated from the Hebrew, is of high literary quality. In a number of cases the method of translation and the vocabulary make it possible to distinguish more than one translator in the longer books such as Jeremiah and Ezekiel.

The importance of the Septuagint, apart from its interest as the oldest biblical translation of any scope, lies in the fact that it is the earliest witness to the Hebrew text, before the latter was standardized 1,000 years later by the Masoretes (*q.v.*). It does not follow, however, that the Septuagint reading is preferable in all cases where it diverges from the Hebrew. The translators sometimes made mistakes because they did not know enough Hebrew, occasionally they changed the meaning in order to make it suit the local Egyptian situation, and often they interpreted instead of translating. So the Septuagint can be used to clarify the

Hebrew text only in a limited way and only after examining the methods of translation book by book.

Further, the use of the Septuagint is hindered by the unsatisfactory nature of its own text. It is contained in a few early, but not therefore necessarily reliable, manuscripts, written in uncials (*see* BIBLE: *Canon and Text*), the best known being the Codex Vaticanus (B) of the 4th century A.D., the Codex Alexandrinus (A) of the 5th century A.D., and the Codex Sinaiticus (ℵ or S) of the 4th century. There are numerous papyrus fragments written earlier than the uncials, and many later manuscripts.

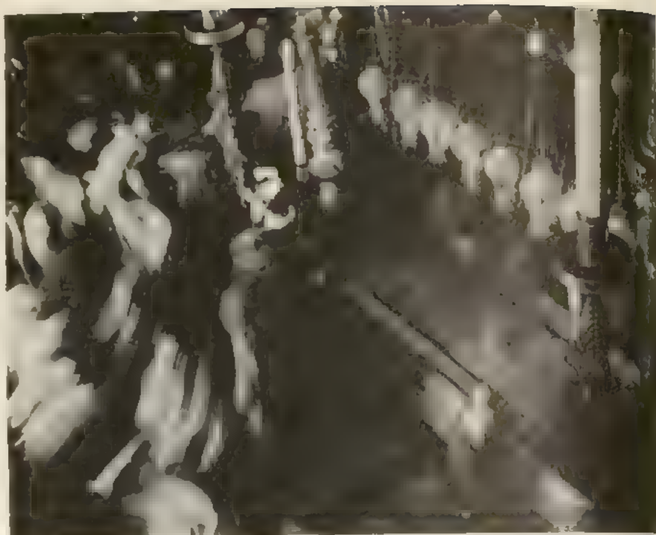
The first copy of the Septuagint to be printed was in the Complutensian Polyglot in 1514–17 (*see* POLYGLOT BIBLES), but it was not put in circulation until 1522, by which time the actual *editio princeps* had appeared from the Aldine Press at Venice in 1518. H. B. Swete's edition in three volumes (1887–94, revised 3rd and 4th ed. 1907–12) gives the text of B and of A or ℵ where B is lacking, with variants from a limited number of manuscripts. It is thus not a critical edition but a selection based on the uncial manuscripts and on manuscripts available in facsimile or in print. E. A. Brooke and N. McLean's edition (1906–   ) has practically the same text as Swete, but the critical apparatus mentions every known uncial manuscript together with a selection from the later manuscripts and from some early translations based on the Septuagint as well as from patristic quotations. An edition on a similar scale by A. Rahlfs under the auspices of the Göttingen Academy of Science (1931–   ) gives a critically compiled text and, in the critical apparatus, the readings of groups of manuscripts in families corresponding to the different recensions which the Septuagint text unmistakably exhibits. (Rahlf's two-volume edition of 1935 gives the same text but omits most of the critical apparatus.)

As a result of the research of P. E. Kahle, emphasis in biblical studies falls on the gradual development of the different parts of the Old Testament translation. It is seen that official control which led to an authoritative text came rather at the end than at the beginning of its development. It is possible that the Christian Church—and modern knowledge of the Septuagint depends almost entirely on the material used by the church—took over one of several Jewish texts in circulation. The lucky finds of fragments (Papyrus Fouad; John Rylands fragments) from the Septuagint of Jewish origin in Egypt and near the Dead Sea show how dangerous, if not impossible, is the attempt made by Paul Antoine de Lagarde and his followers to reconstruct the "original" Septuagint.

BIBLIOGRAPHY.—Editions are mentioned above; manuscripts listed in A. Rahlfs, *Verzeichnis der griechischen Handschriften des Alten Testaments* (1914); concordance by E. Hatch and H. A. Redpath, 2 vol. with supplement (1897–1906; reprinted 1954). Eng. trans. by L. C. L. Brenton (1844, frequently reprinted). *See* also H. B. Ziegler, *Die Septuaginta. Erbe und Auftrag* (1962). (P. A. H. DE B.)

SEPULCHRE, HOLY, the tomb in which Jesus was buried, and so the name of the church built on the traditional site of Jesus' crucifixion and burial. Since, as John 19:42 says, "the tomb was close at hand," near the cross, the church has been planned to enclose the site of both cross and tomb (*see* CALVARY).

The Church of the Holy Sepulchre (more correctly, Anastasis, or "Resurrection") lies in the northwest quarter of modern walled Jerusalem. Constantine the Great first built a church on the site. It was dedicated about A.D. 336, burned by the Persians in 614, restored by Modestus, destroyed by the caliph al-Hakim about 1009, and restored by the Byzantine emperor Constantine Monomachus. In the 12th century the crusaders carried out a general rebuilding of the church. Since then, because of fire, war, earthquake, and deterioration, frequent repair, restoration, and re-



SABINE WEISS—RAPHO GUILLUMETTE

PILGRIMS MOVE PAST THE MARBLE SLAB THAT COVERS THE SUPPOSED TOMB OF CHRIST IN THE CHURCH OF THE HOLY SEPULCHRE, JERUSALEM

modeling have been necessary. The present church dates mainly from 1810. Though structurally weak and aesthetically unsatisfying, the church is the focus of great Christian interest. Various Christian groups, including the Greek, Roman, Armenian, and Coptic churches, control parts of the structure and conduct services regularly. The main features of the church are the *Martyrion*, on the supposed site of Jesus' crucifixion, and the rotunda over the tomb shown as the place of his burial and resurrection; auxiliary chapels commemorate events of Jesus' passion and resurrection.

This site, thus, has been continuously recognized since the 4th century as the place where Jesus died, was buried, and rose from the dead. But whether it is the actual place of his crucifixion and burial has been hotly debated. Two main questions are involved. The first of these is whether Christians of the first three centuries could and did preserve a continuous authentic tradition as to just where these events occurred. The Jerusalem church fled to Pella about A.D. 66. Titus destroyed Jerusalem in A.D. 70. In A.D. 135 Hadrian again destroyed the city and in its place built the pagan city Aelia Capitolina. It is said that over the place where the tomb of Jesus is now shown he built a shrine of Venus, possibly to stop Christians from visiting the spot in memory of Jesus' death. But it is not certain that Christians in the apostolic age continually focused attention on this spot as the exact place where Jesus died and was buried, and times of war, destruction, and confusion could have prevented the preservation of such exact information.

The other main question involves the course of the second north wall of ancient Jerusalem. The first wall ran eastward from near the present Jaffa Gate to the west wall of the Temple area. The second wall, according to Josephus (*Wars*, v, 4, 2), started from the Gennath Gate, near the western end of the first north wall, circled north and east to enclose an area north of the first wall, and ended at Antonia, at the northwest corner of the Temple area. The third wall was built later than the time of Jesus, and so throws no light on where Jesus died and was buried. Some archaeological remains on the east and south sides of the Church of the Holy Sepulchre are widely interpreted to mark the course of the second wall; if so, the site of the church lay just outside the city wall in the time of Jesus, and could be the actual place of his crucifixion and burial. This site probably did lie outside the city wall at that time; it may well be the very place where Jesus died and was buried; no rival site is supported by any real evidence; but it is not certain that knowledge of the exact spot was continuously preserved in the early, turbulent days of the church, so complete certainty is now unattainable. *See* also PALESTINE: *The Holy Places*.

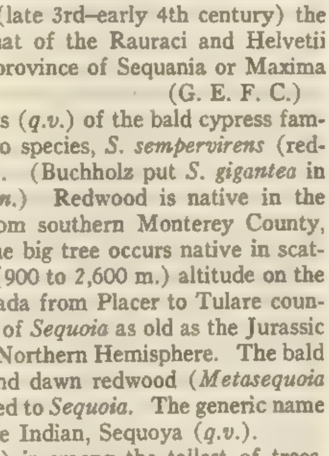
SEQUANI, a Celtic people who by Caesar's day were occupying the territory between the Saône, Rhone, and Rhine rivers, with their centre at Vesontio (Besançon). Quarrels with the Aedui (*q.v.*) over tolls on the Saône led them to call in the German Ariovistus, who defeated the Aedui (perhaps in *c.* 61 B.C.), but occupied Sequanian territory in modern Alsace and gradually raised his demands. Sequanian nobles supported the Aedui in appealing to Caesar in 58, but after Caesar had expelled the Germans he compelled the Sequani to restore all Aeduan land they had seized. The Sequani joined the Gallic revolt led by Vercingetorix in 52, but after its suppression by Caesar they were apparently not penalized. Under the empire they were part of Gallia Belgica and ruled by magistrates on the Roman model; Vesontio (possibly a Latin colony) had walls and important public buildings, though the well-known arch (Porte Noire) which survives was probably built after A.D. 150 (*see* BESANÇON). Like the Aedui the tribe supported Julius Vindex in 68, and next year opposed the Treveri in their attempt at an independent Gaul.

In Diocletian's reorganization (late 3rd–early 4th century) the territory of the Sequani, with that of the Rauraci and Helvetii to the east, became the separate province of Sequania or Maxima Sequanorum. (G. E. F. C.)

SEQUOIA, a genus of conifers (*q.v.*) of the bald cypress family (Taxodiaceae), comprising two species, *S. sempervirens* (redwood) and *S. gigantea* (big tree). (Buchholz put *S. gigantea* in a separate genus, *Sequoiadendron.*) Redwood is native in the fog belt of the Coast Ranges from southern Monterey County, Calif., to southern Oregon, and the big tree occurs native in scattered groves at 3,000 to 8,500 ft. (900 to 2,600 m.) altitude on the westerly slopes of the Sierra Nevada from Placer to Tulare counties in California. Fossil remains of *Sequoia* as old as the Jurassic period are widely dispersed in the Northern Hemisphere. The bald cypress (*Taxodium distichum*) and dawn redwood (*Metasequoia glyptostroboides*) are closely related to *Sequoia.* The generic name commemorates the great Cherokee Indian, Sequoya (*q.v.*).

The redwood (*S. sempervirens*) is among the tallest of trees, often exceeding 300 ft. (91 m.), and the trunk diameters range to 15 ft. (5 m.), or exceptionally to 20 ft. (6 m.), measured above the swollen bases. The insect-, fungus-, and fire-resistant bark is reddish-brown, fibrous, deeply furrowed, and may be 12 in. (30 cm.) or more thick on old trees. The bases of the trees form massive buttresses, and hemispherical burls occur on some trunks. Beautifully grained veneer, bowls, trays, and turned articles are made from large burls; small burls, sawed from the tree and placed in a tray of water, send forth decorative green sprays. Young trees are conical in form and clothed to the ground with densely leaved, slightly drooping branches; in age the lower limbs fall away, leaving a columnar clear trunk to a height of 100 ft. (30 m.) or more. When a tree is cut, numerous shoots arise from the sapwood below the cut surface and grow into trees in 30 to 60 years if protected from fire; vigorous leaders grow as much as eight feet in length during a year. The needlelike leaves are dark green above, whitish beneath, one-third to one inch long, arranged in two-ranked sprays, and remain functional three to seven years. Cones are one to two inches long and produce tremendous seed crops, but germination rarely exceeds 25%. Thus seedlings are rare in the forests and reproduction is mainly vegetative.



JOHN MARKHAM

FOLIAGE AND CONES OF REDWOOD (SEQUOIA SEMPERVIRENS)

The sapwood is thin, white, and decays readily, but heartwood is reddish-brown, evenly fine grained, strong, and durable. It resists attack by fungi, termites, and other insects. Some redwood fence posts have lasted at least 50 years.

Heavy cutting beginning in the 1860s has drastically reduced the original 1,454,000 ac. (588,434 ha.) of redwood forests, but extensive stands still exist. Logging continues, but the annual cut dropped after World War II. Yields run about 150,000 bd.ft. per acre in normal stands, but cuts as high as 1,500,000 bd.ft. per acre are on record. Second-growth timber on favourable sites produces nearly 140,000 bd.ft. per acre in 60 years, the greatest volume growth of any known softwood tree in the world.

The big tree (*S. gigantea*) is the largest of all trees in bulk and long was reputed to be the oldest living thing. Many reports about the great age of the trees were exaggerations, for the largest stumps accurately examined yielded counts of about 4,000 years. The largest specimen is the General Sherman tree in Sequoia National Park, measuring 101.5 ft. (31 m.) in circumference at the base; a mean base diameter of 32.2 ft. (10 m.); diameter 27 ft. (8 m.), 8 ft. (2 m.) above the ground; diameter 18.5 ft. (6 m.), 100 ft. (30 m.) above ground; 272.4 ft. (83 m.) tall; diameter of largest branch (130 ft. [40 m.] above ground) 6.5 ft. (2 m.); total estimated weight 6,167 tons. A few specimens are over 300 ft. (91 m.) high, but have less bulk than the General Sherman tree.

AUTHENTICATED NEWS

BIG TREE (SEQUOIA GIGANTEA) IN KINGS CANYON NATIONAL PARK, CALIF.

Although several big tree groves were cut, the lumber is more brittle than that of the redwood; since the lumber is less desirable, it has been easier to save the big trees from destruction. Most of the 70 distinct groves now are under the protection of state or national forests and parks. The groves contain as few as 4 and as many as 3,500 mature trees each, and seedlings and young trees are very numerous in some of the groves.

The earliest-known mention of the big trees is a narrative of Capt. Joseph Walker's expedition of 1833 published in 1839. Though other persons must have seen the big trees in the years following, the Calaveras grove did not become known generally till 1852.

SEQUOIA NATIONAL PARK, a reservation of 386,863 ac. (156,680 ha.) in the Sierra Nevada Mountains of California, was established by act of the U.S. Congress on Sept. 25, 1890, in order to protect groves of *Sequoia gigantea*, giant sequoia or big tree, among the largest members of the vegetable kingdom. Until specimens of bristlecone pine were discovered to be older, *Sequoia gigantea* was also believed to have the oldest living members of any species on earth. *Sequoia gigantea* is not known to exist anywhere outside the Sierra Nevadas. It does not reproduce rapidly, very few of the seeds taking root. The great girth and lack of taper of mature specimens of *Sequoia gigantea* account for its

achieving a greater bulk than any other species, although other species grow taller. The General Sherman tree is the largest in the park (*see* Sequoia).

Repeated efforts have been made to save the redwoods from the lumberman's saw. The Mariposa Grove, adjacent to Yosemite Valley, was set aside by Congress in 1864. The General Grant National Park was created in 1890 and assimilated in Kings Canyon National Park when the latter was created in 1940. Other groves are in California state parks. Sequoia National Park is accessible by automobile and bus from Fresno, Visalia, or Tulare. Accommodations are available at Giant Forest throughout the year. Lodges and camping areas are open elsewhere from June to September. Fishing, hiking, and horseback riding are among the recreations. (J. E. Cl.)

SEQUOYA (Sequoyah) (?–1843), a half-blooded Cherokee Indian who created the Cherokee alphabet, the only man in history known to have developed an entire alphabet or syllabary. Born at a Tuskegee village on the Tennessee River in what later became the state of Tennessee, Sequoya was probably the son of a British trader named Nathaniel Gist. Reared by his Indian mother, he never learned to speak, read, or write English. He was, however, an accomplished silversmith, painter, and warrior, and served with the U.S. Army in the Creek War in 1813–14. Perhaps as a result of wounds received in the Creek campaigns, he became crippled in one leg, which enhanced his inclination toward a contemplative life.

Like many Indians of his era, Sequoya wished to learn the secret of the white men's superior power. He became convinced that their secret was written language, which enabled them to accumulate and transmit more knowledge than was possible for a people dependent on memory and word of mouth. About 1809 Sequoya began working systematically to develop a written language for the Cherokees, experimenting first with pictographs and then with symbols representing the syllables of the spoken language. His young daughter helped him to identify the Cherokee syllables. For symbols, he adapted letters from an English speller and, probably, from printed words in Greek and Hebrew obtained from missionaries. By 1821 he had perfected 86 letters, representing all the syllables of the Cherokee language.

Sequoya convinced his tribesmen of the utility of his syllabary by transmitting messages between the Cherokees of Arkansas (with whom he went to live) and those of the east, and by teaching his daughter and selected youths of the tribe to write. The simplicity of his system enabled pupils to learn it rapidly, and soon Cherokees throughout the nation were teaching it to one another. The tribe established schools where Sequoya's alphabet was taught, and published books and newspapers in the Cherokee language.

Sequoya's name (spelled Sequoia) was given to the giant redwoods of California and to the Sequoia National Park in California. In recognition of Sequoya's contribution to the early development of Oklahoma, that state chose him as one of its two representatives in Statuary Hall in the national capitol at Washington, D.C.

See Grant Foreman, *Sequoyah* (1959). (M. E. Yo.)

SERAING, an industrial town in the province of Liège, Belgium, lies on the Meuse River, 6 mi. (10 km.) upstream from Liège town. Pop. (1961) 41,239. In the town are an engineering and technical institute, the royal lyceum, the royal athenaeum, and the statue of John Cockerill (1790–1840). The château of the prince bishops of Liège houses the amalgamated Cockerill-Ougrée Company (1955). In 1835 an engineering enterprise founded earlier by John Cockerill, in partnership with King William I of the Netherlands, constructed at Seraing the first steam locomotive on the continent. Seraing is a principal centre of Belgium's metallurgical and machine-building industry, and there are also glassworks.

SERAMPUR, a town in Hooghly District, West Bengal, India, on the right bank of the Hooghly River, 4 mi. (6 km.) N of Calcutta. Pop. (1961) 91,521. Originally a Danish settlement, the town was acquired by the East India Company in 1845. A Baptist mission, which began work in Serampur in 1793, did much to spread knowledge of Christianity in Bengal. Serampur College (1818) owes its establishment to three Baptist missionaries who were the first people in India to cast types in the Indian alphabets, and the earliest newspapers in Bengali were issued from the press at Serampur in 1818. The first paper mill in India was built at Serampur in the 1870s. The town, which has a college of textile technology and two other colleges, both affiliated with Burdwan University, is an important centre of the cotton and jute industry. (S. P. C.)

SERAO, MATILDE (1856–1927), Italian novelist, one of the best of the southern Italian realist school of writers, was born at Patras, Greece, on March 7, 1856. She spent most of her life in Naples, where she founded and directed a daily paper, *Il Giorno*. She died in Naples on July 25, 1927. Many of her innumerable novels and short stories were very popular, and the best of them, which include *La virtù di Checchina*, *La conquista di Roma*, and *Il paese di Cuccagna*, depict with minute accuracy and feminine tenderness the life of the humble people.

See B. Croce, *La letteratura della nuova Italia*, vol. III (1929); M. Sandri, *M. Serao* (1922).

SERAPHIM, SAINT, of Sarov (Prokhor Isidorivich Moshnin) (1759–1833), is, together with St. Sergius (*q.v.*) of Radonezh, perhaps the saint who most clearly embodies all the features of Russian Orthodox monastic spirituality. He was born on July 19 (old style), 1759, in Kursk, the son of a merchant. Unusually devout even as a boy, on Nov. 20 (O.S.), 1779, he entered the Sarov monastery (in the Oka region of East Russia). On Aug. 13 (O.S.), 1786, he was consecrated as a monk and took Seraphim as his name in religion. He received priestly orders in 1793 and, until he left the monastery, celebrated the Eucharist daily, which was rare in 18th-century Russia. From 1794 to 1810 he lived as a hermit in a hut in the woods, for some years spending the night in prayer as a stylite on a great stone and from 1807 in complete silence. He constantly carried the Gospels in a sack on his back, in order to read them daily and to be reminded of the weight of the cross on Christ's back. Following Matt. 5:39, he did not defend himself against an attack by robbers and as a result was permanently crippled. He attributed his recovery to the Virgin Mary, who (as in earlier illnesses) appeared to him in a vision.

From 1810 to 1825 he lived as a recluse in the monastery of Sarov. In the latter year he left his cell on the command of the Virgin Mary and devoted himself to pastoral care and spiritual healing. He told his flock, most of them laity, that the most important aim in life was to obtain the "gift of the Holy Ghost," through a spiritual life in the old monastic tradition, which Seraphim was the first to extend also to laymen. He died at Sarov on Jan. 13, 1833 (O.S.), and was canonized on July 19 (O.S.), 1903.

Bibliography.—V. Zander, *Saint Seraphim de Sarov* (undated); I. Smolitsch, *Leben und Lehre der Starzen*, 2nd ed. (1952); I. Kologrivof, *Essai sur la sainteté en Russie* (1953); G. P. Fedotov (ed.), *A Treasury of Russian Spirituality* (1952). (F. v. L.)

SERAPHIM, six-winged beings seen by Isaiah in his vision (Isa. 6:2–6) standing by the throne of the Lord and singing his praises. The Hebrew term is essentially an adjective meaning "winged" or "fiery ones." The singular saraph occurs in Num. 21:6–8 and in Deut. 8:15 and Isa. 30:6, mentioned in the last case in association with scorpions. The concept apparently derives from ancient Near Eastern folklore, and the seraphim have been identified with the six-winged figure, holding a serpent in each hand, portrayed on a relief at Tell Halaf, one of the oldest sites in north Mesopotamia.

In early Christian times the seraphim came to be considered as a category of angels, comparable to the cherubim, and in the nine "choirs" of angels they held the highest rank. In Christian liturgy, the best-known use of the word is in the *Te Deum:* "To thee Cherubim and Seraphim continually do cry, Holy, Holy, Holy, Lord God of Sabaoth." *See* Angel.

SERAPIS: *see* Sarapis.

SERBIA (Srbija), a country of southeastern Europe, in the north of the Balkan Peninsula. After a long history of great vicissitudes, which constitute the subject of the present article, Serbia, with an area expanded to 49,528 sq.mi. (128,278 sq.km.)

as a final result of World War I, was in December 1918 merged in the Kingdom of the Serbs, Croats, and Slovenes, which in 1929 changed its name to Yugoslavia (*q.v.*). When Yugoslavia was reorganized in 1946, Serbia became one of the component republics of the federation, with an area of 34,116 sq.mi. (88,361 sq.km.), including the autonomous region of Vojvodina (*q.v.*) in the north and that of Kosovo-Metohija (*q.v.*) in the south. For physiography *see* YUGOSLAVIA.

The Serbs use a Cyrillic alphabet, rather than the Latin one with diacritical marks, as used by the Croats, whose language is scarcely different from Serbian (*see* SERBO-CROATIAN LANGUAGE). In this article the latter alphabet is used for Serbian names, instead of the English system of transliteration from the Cyrillic: for instance *c* instead of *ts; č* or *ć* instead of *ch; ja* instead of *ya; š* instead of *sh; ž* instead of *zh*.

The Serbs (*Srbi*, singular *Srbin*), who belong to the South Slav group of the Slavonic peoples (*see* SLAVS), arrived in the Balkans during the 7th century A.D. The etymology of this name, which first occurs, in the form Sorabi, in the *Frankish Annals* for the year 822, is obscure; it must be remarked that the Slavs of Lusatia (*q.v.*) similarly call themselves Sorbs.

In their Balkan settlements, along the Piva, Tara, upper Drina, Ibar, Lim, and Western Morava rivers, the Serbs did not at once form a united state. Clans more or less related to each other occupied a certain territory under the political and military leadership of a *župan*. Attempts by one *župan* after another to subjugate his neighbours led to much bloodshed; and the custom of the ancient Slavs, whereby a *župan* was succeeded by the eldest surviving member of his family, not necessarily by his own son as he might naturally wish, gave rise to further conflict.

The House of Višeslav.—The first *župan* whose name is recorded was Višeslav (Visheslav), who was living *c.* A.D. 780. He had a son, Radoslav, whose grandson Vlastimir fought a war against the Bulgars (*c.* 850). Vlastimir's son Mutimir accepted Orthodox Christianity (*c.* 879); and the work of evangelization was carried forward by disciples of SS. Cyril and Methodius (*see* CYRIL AND METHODIUS, SAINTS), in particular by SS. Clement and Naum, who founded Serbia's first monasteries on the Prespa and Ohrid lakes.

After Mutimir's death (*c.* 890) the Byzantines and the Bulgars began a struggle for Serbia. Peter Gojniković, who ruled from 892 as the successor of his cousin Prvoslav (Mutimir's son), adopted a pro-Byzantine policy, but was lured under the promise of safe conduct to an interview with the Bulgarian tsar Simeon, who then arrested him and took him in shackles to die a prisoner in Bulgaria. The Bulgars set up Mutimir's grandson Paul as ruler of Serbia (917–920). When Paul initiated a *rapprochement* with Constantinople, they replaced him with Zacharias, another of Mutimir's grandsons, who had originally been the Byzantines' candidate against Paul but had fallen into Simeon's hands. When Zacharias likewise made new approaches to the Byzantines, Simeon drove him into exile in Croatia (924).

On Simeon's death, in 927, Časlav (Chaslav), a great-grandson of Vlastimir, escaped from captivity in Bulgaria and soon made himself ruler over most of the Serbs and was able to annex Bosnia, but had to acknowledge the Byzantine emperor as his suzerain. He was killed in battle against the Magyars (Hungarians) in 960. Bosnia soon detached itself from the rest of the Serbian territory.

Zeta and Raška.—One of the Serbian territories was Duklja, the ancient Dioclea, later called Zeta (*see* MONTENEGRO). Its prince, Vladimir, was captured by the Bulgarian tsar Samuel in 989 but was allowed to return to his country after marrying Samuel's daughter Kosara. On May 22, 1016, however, he was treacherously murdered at the behest of Samuel's successor Vladislav.

The subsequent course of events is not well known. Prince Vojislav of Travunija (Trebinje), a cousin of Vladimir, led an insurrection against Byzantine overlordship, but was defeated (1036) and taken to Constantinople. Escaping to the mountains of Zeta, he led a second rising, which was successful. Vojislav's son Michael (Mihajlo), who succeeded him *c.* 1050 and was later styled king, sent his son Bodin to help an anti-Byzantine insurrection in the region of Skopje (Skoplje) in 1073, whereupon the insurgents proclaimed Bodin tsar of the Bulgars. Though Bodin fell eventually into Byzantine hands, he was set free by the Venetians and returned to Zeta to succeed his father as king (*c.* 1081). He added Raška (Rashka, on the Ibar River) and Bosnia to his dominions. In another war against the Byzantines he was again taken prisoner (1091). Freed again, he reinstated himself as king, and died in 1101.

Raška, detached from Zeta before the end of the 11th century, produced its own *župan*, Vukan, against whom the Byzantine emperor Alexius I conducted three campaigns. The *župan* Uroš (Urosh) I, recorded *c.* 1114, may have been a nephew of Vukan and was probably the father of the *župan* Uroš II, against whom the emperor Manuel I fought a war in 1149. Manuel destroyed Uroš II's capital, drove him to refuge in the mountains, and, in 1150, attacked him again, forcing him this time to swear allegiance. By *c.* 1155, however, a certain Desa was ruling Raška in the place of Uroš II, whose cause Manuel then supported.

The Nemanja Dynasty.—About 1167 Stephen (Stefan) Nemanja (Nemanya) became grand *župan* of Raška, under Byzantine suzerainty. When he joined the Venetians against Manuel in 1171, a Byzantine army was sent to install his brother Tihomir in his place, but Nemanja won a battle near Kosovo, and Tihomir perished. Defeated by the Byzantines in 1172, Nemanja obtained pardon from Manuel; but after Manuel's death (1180) he began war again, conquering several Byzantine places on the Adriatic coast. He allied himself with Ivan Asen I, founder of the Second Bulgarian Empire; and in 1189–90 he took Skopje, Prizren, and Tetovo. Later in 1190 he was defeated by the emperor Isaac II on the Morava River; but even so he retained Kosovo, Peć, Prizren, Bar, Skadar (Shkodër), and Kotor, while his son, Stephen, was married to Isaac's niece, Eudocia. After Isaac was deposed, Nemanja abdicated (March 25, 1196) and became a monk. He died in 1200, on Mount Athos.

Nemanja left his throne, not to his eldest son, Vukan, but to his second son, Stephen, probably because Stephen's father-in-law had become Byzantine emperor as Alexius III. Apart from Vukan's resentment, Stephen had to face danger from the Bulgars, from the Hungarians, and from the Latin Empire, which the leaders of the Fourth Crusade set up in place of the Greek in 1204. He received invaluable support, however, from his youngest brother, Sava, the future saint, one of the greatest personalities in Serbian history. Sava returned to Serbia from Mount Athos, where he had been living as a monk before Nemanja's retirement; and in 1219 he was consecrated as the first archbishop of an autocephalous Serbian Orthodox Church. While it is generally accepted that Stephen received a royal crown from Pope Honorius III in 1217, Serbian sources state that he was crowned king of the Serbs by Sava in the Church of the Seven Doors at Žiča in 1220. Known as Stephen the First Crowned, he died *c.* 1228.

The succeeding kings were Stephen's sons Stephen Radoslav (reign 1228–34), Stephen Vladislav (1234-43), and Stephen Uroš I (1243–76). Uroš in 1252 made war against the Adriatic city of Dubrovnik, which soon came to terms with him; but in 1253 Dubrovnik allied itself with the Bulgars, whose forces penetrated Serbia as far as the Lim River. For that reason the seat of the Serbian archiepiscopate was transferred from Žiča to Peć. Peace, however, was made in 1254. In a war against the Nicean emperor Theodore II Lascaris, Uroš occupied Skopje, Prilep, and Kičevo, but not for long. Taken prisoner in war against the Hungarians (1268), he obtained his freedom by promising to accept as coruler his son Stephen Dragutin, who was married to Elizabeth, granddaughter of the Hungarian king Béla IV. His violation of this promise caused Dragutin to revolt; and Uroš, defeated in battle in 1276, retired as a monk to Hum (Hercegovina), where he died.

Having maintained good relations with his neighbours for most of his reign (1276–82), Dragutin joined Charles I of Naples and Sicily and the Venetians in their anti-Byzantine alliance of 1281. Then he broke his leg in a fall from his horse. Taking this a judgment from God, he abdicated in 1282, in favour of his brother Milutin (also reckoned as Stephen Uroš II). Later, however, he claimed that he had merely made Milutin regent and had reserved

FIG. 1.—TERRITORIAL EXPANSION DURING THE NEMANJA DYNASTY

the eventual succession to his own descendants (*see* below). Though Dragutin was granted Belgrade, Mačva, and northeastern Bosnia by his brother-in-law László IV of Hungary, he finally became a monk, dying in 1316.

Milutin's reign (1282-1321) marks the rise of Serbia in the international field. A few months after his accession he conquered Skopje, Tetovo, Ovče Pole, and Pijanec from the Byzantines. An army sent against him by the emperor Andronicus II was defeated, and the Serbs advanced to the walls of Strumica, Prilep, and Ohrid. Peace was not concluded till 1299, when Milutin married the emperor's daughter Simonis, and the Byzantines formally ceded the conquered lands as her dowry. Planning a new war against the Byzantines, Milutin in 1308 made an alliance with the ambitious French prince Charles (*q.v.*) of Valois and entered into relations with Pope Clement V, but this project came to nothing when Charles gave up his designs on the Eastern Empire. A Hungarian attack on Serbia in 1319 was without effect.

Internally, Serbia's mineral resources were exploited, commerce thrived, and about 40 churches were built during Milutin's reign. There were two political crises, however. The first, arising from Dragutin's dynastic claims for his sons, was overcome in 1312. The second was the rebellion (1314) of Milutin's own son and heir apparent, Stephen (Uroš III, otherwise called Stephen of Dečani, or Stefan Dečanski), who was captured, condemned to be blinded, and exiled but was later allowed to return to Serbia.

Milutin died of apoplexy on Oct. 29, 1321. His younger son Constantine and Dragutin's son Vladislav then contested the throne. Suddenly, however, the rumour spread that the blinded Stephen had miraculously recovered his sight. Popular sympathy was with him as a martyr, and at Epiphany 1322 he was crowned king, while his son Stephen Dušan (Dushan) was also crowned as "young king" or heir apparent. Constantine was killed soon afterward, and Vladislav gave up the struggle. The Byzantines and the Bulgars allied themselves against Serbia in 1330; but the Bulgars were decisively defeated at Velbuzhd (Kyustendil) on July 28, when their tsar Michael Shishman was killed. The Byzantine emperor Andronicus III thereupon abandoned his campaign.

There followed a quarrel between the Serbian king and his heir. In the spring of 1331 they seemed to be reconciled, but in the following summer Dušan dethroned his father, who died soon afterward (Nov. 11, 1331). Dušan's sole rule now began. A man of magnificent physique, energetic, resolute, and ambitious, he fascinated his subjects and could lead them wherever he wished. Continuing the war against the Byzantines, he forced them to cede some Macedonian territory in 1334. The Byzantine civil war, which broke out in 1341, gave him a new opportunity. Having conquered all Macedonia as far eastward as Philippi, with the exception of Salonika, he assumed the title of "tsar [emperor] of the Serbs and Greeks" in 1345. He then procured the establishment of the Serbian Church as an independent patriarchate (March 1346); and on Easter Day, 1346, he had himself crowned as tsar at Skopje by his new patriarch. Dušan then turned his attention westward and southward, occupying Albania, Epirus, Aetolia (which gave him a foothold on the Gulf of Corinth), and finally Thessaly. He was dreaming of taking Constantinople when he died on Dec. 20, 1355.

The tsar Uroš, Dušan's son and successor, was a weak man. His reign (1355–71) saw the decline of Serbian power. The process of disruption was begun by Simeon, Dušan's half brother: he proclaimed himself "tsar of the Greeks, Serbs, and all Albania" and ruled Epirus and Thessaly in independence from 1359. Other provincial rulers asserted themselves in the 1360s: the Balšić family in northern Albania and along the Adriatic coast; Nikola Altomanić at Rudnik and southwestward from there; and the brothers Vukašin and Uglješa in Macedonia. Vukašin, ruling Skopje, Prizren, Prilep, and Tetovo, assumed the title of king in January 1366. Campaigning against the Ottoman Turks, who had first appeared in the Balkans in the 1340s, Vukašin and his brother were killed in the Battle of the Maritsa River, near Adrianople, in the stormy night of Sept. 25–26, 1371, when the Serbs sustained a terrible defeat still proverbially remembered as a national disaster. Two months later, Tsar Uroš died.

Prince Lazar and the Battle of Kosovo.—The foremost of the princes who took over the succession of Uroš in 1371 was Lazar, a member of the Hrebeljanović family and, by marriage, a relative of the House of Nemanja. The Balšić family, however, remained powerful; Vukašin's son Marko (the Marko Kraljević of Serbian legend) also had some territory; the Dejanović family were strong in eastern Macedonia; and Vuk Branković dominated the Kosovo region. With help from Tvrtko of Bosnia, Lazar overthrew Nikola Altomanić in 1373 and partitioned his territory with Tvrtko.

Though Tvrtko's subsequent assumption of a royal title (*see* BOSNIA-HERCEGOVINA) implied some diminution of Lazar's status

the two were in agreement on the need to cooperate against the Turks. Having reduced most of Bulgaria and Macedonia to vassality, Sultan Murad I was demanding tribute from the Serbs. Lazar resisted, and Murad, who attacked Serbia and captured Niš in 1386, was halted at Pločnik. In 1389, however, Murad led another invasion, and on June 15 the Battle of Kosovo was fought: Murad himself was killed, but the Serbs were catastrophically defeated. Lazar was taken prisoner and beheaded. The Battle of Kosovo, symbolizing the choice of death rather than compromise with the enemy, is one of the permanent memories of the Serbian national consciousness.

The Despotate.—Lazar's son Stephen succeeded to the Serbian principality in 1389 as a vassal of Sultan Bayazid I. He thus took part in several Turkish campaigns, fighting at the Battle of Rovine against the Walachians (1395), at the Battle of Nicopolis against the crusaders from Hungary (1396), and at the Battle of Ankara, where Bayazid's army was defeated by Timur (1402). Stephen, returning home via Constantinople, accepted the title of despot (that is, lord) from the Byzantine regent John VIII Palaeologus. The discomfiture of the Turks gave him a freer hand in Serbia. After nominating his nephew George Branković as his successor, he died on July 19, 1427.

George Branković was a highly cultured man and an experienced soldier. The Turks, whose power was growing again, resented George's friendly relations with Hungary, and in 1439 Sultan Murad II took the new Serbian capital, Smederevo, and captured two of George's sons, who were later blinded. George went to Hungary for help; and in autumn 1443 he and János Hunyadi (*q.v.*) led a large army against the Turks. Having advanced as far as Sofia, the allies might have taken Adrianople if the cold weather and the shortage of food had not induced Hunyadi to retreat to Hungary for the winter. George then made a separate peace with Murad, who recognized him as despot of the restored Serbia.

When Hunyadi returned to the Balkans with the Hungarian king Ulászló I (Władysław III of Poland), in 1444, he was completely defeated at Varna; and his expedition of 1448 ended in disaster at Kosovo. These two Hungarian reverses were due in part to the attitude of George Branković, who was no longer willing to commit himself hastily against the Turks. Even so, Sultan Mohammed II, after his conquest of Constantinople in 1453, decided to attack Serbia. After a first campaign in 1454, he captured Novo Brdo in 1455, while George was in Hungary seeking help again. George might have received it more easily if he had become a Roman Catholic, but this he steadfastly refused to do, lest he should forfeit the respect of his Orthodox subjects. He died on Christmas Eve 1456.

After the short reign of George's son Lazar (1456–58), there was an attempt to save the remnant of Serbia by marrying Lazar's daughter Jelena to the Bosnian prince Stephen Tomašević. But the sultan attacked Serbia again and took Smederevo on June 20, 1459. That was the end of Serbia as a territorial power.

From 1389, however, the Serbs had been migrating to Hungarian territory, and the numbers of such migrants increased after 1459. The Hungarians welcomed them as fighters against the Turks. Matthias (*q.v.*) Corvinus granted the nominal title of despot in 1471 to George Branković's grandson Vuk (d. 1485) and in 1486 to the latter's first cousin George (d. 1496 or 1497), from whom it passed to his brother John (d. 1502). From 1504, it was borne by members of other families.

Sultan Suleiman I the Magnificent conquered Šabac in 1521 and Belgrade a few months later. Crossing the Sava River, the Turks devastated Srem. The Serbs Radić Božić and Pavle Bakić took a leading part in the resistance, but Suleiman's great victory over the Hungarians at Mohács in 1526 heralded the subjection of all the Serbs to Turkish rule. John (Jovan) Nenad, known as "the Black Man," who won a large following among the Serbs of Hungary and assumed the title of tsar, was killed in 1527; and ten years later Pavle Bakić, the last titular despot, was killed in battle.

Turkish Rule.—All land in Serbia became the property of the sultan, who entrusted it to *spahis*, military tenants who held it from him in return for their services. The Serbs themselves were bondslaves of the land, most of the revenue being the perquisite of the *spahis*. In the early period of the Turkish occupation, however, there took place an event of great significance for the Serbs, namely the restoration of the Serbian patriarchate at Peć (1557). The first of the new patriarchs was Makarije, brother of the Turkish grand vizir Mohammed Pasha Sököllü (Sokolović). With a large territorial jurisdiction, the patriarch was the personification of national survival as well as the spiritual head of his people.

The defeat of the Turks outside Vienna (1683) was followed by Austrian counteroffensives in the course of which Prince Louis of Baden advanced as far south as Kosovo. The Serbs then rose against the Turks; but a new Turkish effort, under the grand vizir Mustafa Köprülü, not only won the country back but also spread such terror that thousands of Serbs, with their patriarch Arsenije III Crnojević migrated to Hungary. For these refugees the Holy Roman emperor Leopold I promulgated a charter (1690), promising to respect their Orthodox religion and guaranteeing them the rights to elect their patriarch. These undertakings, however, were not long observed.

The Banat (*q.v.*), which had a large population of Serbs, was left under Turkish rule, with the rest of Serbia and Bosnia, by the Peace of Carlowitz (Karlovci) in 1699, though other lands of the Hungarian crown were then ceded by the Turks to Austria. The Austro-Turkish war of 1716–18, however, led to the Peace of Passarowitz (Požarevac), whereby Austria obtained both the Banat and also the adjacent part of Serbia (known as Šumadija) south of the Sava and Danube rivers, with Belgrade. After Austria's unfortunate invasion of Turkish Serbia in 1737, the Peace of Belgrade (1739) restored the Turkish frontier on the Sava and Danube.

In 1766 the Turkish government abolished the Serbian patriarchate; but by the Treaty of Kuchuk Kainarji, in 1774 (*see* RUSSO-TURKISH WARS), Turkey formally acknowledged Russia's claims to champion Orthodox and Slav interests in the Ottoman Empire. When Russia and Austria together began another war against Turkey in 1787, the Serbs under Mihajlo Mihaljević formed a free corps in the Austrian service: the Austrians captured Belgrade in 1789, but retroceded it to the Turks at the Peace of Sistova in 1791. The Serbs' disillusionment at Austria's conduct was expressed in the remark of one of Mihaljević's officers, Aleksa Nenadović: "The Serbs should not trust the Germans."

The reforms initiated by the sultan Selim III in the last decade of the 18th century provoked a number of revolts by the reactionary janizaries in the outlying provinces of the Ottoman Empire. At the end of 1801 Haji Mustafa, the Ottoman governor of the pashalik of Smederevo (or of Belgrade; *i.e.*, Serbia), was assassinated by a faction of janizaries, four of whom then assumed power themselves as *dahije*, or deys. Their regime was so tyrannical that the Serbs began to plan insurrection for the spring of 1804. Aleksa Nenadović, unmindful of the strictures that he had made after the Peace of Sistova, wrote a letter appealing for Austrian help, but his letter fell into the hands of the *dahije*, who put him and four other patriots to death (Jan. 23, 1804).
